

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

ANATOMY

HENRY GRAY, F.R.S.

FELLOW OF THE ROYAL COLLEGE OF SURGEONS; LECTURER ON ANATOMY AT ST. GEORGE'S
HOSPITAL MEDICAL SCHOOL, LONDON

EIGHTEENTH EDITION

THOROUGHLY REVISED AND RE-EDITED WITH ADDITIONS

EDWARD ANTHONY SPITZKA, M.D.

PROFESSOR OF GENERAL ANATOMY IN THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA

Illustrated with 1208 Engravings

LEA & FEBIGER
PHILADELPHIA AND NEW YORK

1910

LIBRARY OF MEDICINE

Entered according to the Act of Congress, in the year 1910, by
LEA & FEBIGER
in the Office of the Librarian of Congress. All rights reserved.

THE FIRST EDITION OF THIS WORK
WAS DEDICATED TO
SIR BENJAMIN COLLINS BRODIE, BART., F.R.S., D.C.L.
IN ADMIRATION OF
HIS GREAT TALENTS
AND IN REMEMBRANCE OF
MANY ACTS OF KINDNESS SHOWN TO THE ORIGINAL
AUTHOR OF THE BOOK
FROM AN
EARLY PERIOD OF HIS PROFESSIONAL CAREER

PREFACE.

HENRY GRAY'S *Anatomy*, both in the original and its many succeeding editions, has long been held in high esteem as a thoroughly practical treatise on the subject for the medical student. In the present revision the editor has endeavored to adhere to the plan as much as possible, supplying such facts and views as the advances in the science of anatomy render it necessary to incorporate. At the same time, he has endeavored to curtail descriptions of undue length, and to clarify any obscure or ambiguous passages in the text; so that the essentials are here embodied into a fairly complete account of the structures of the human body and their development. It has also been the editor's aim to achieve the utmost degree of uniformity in the mode of treatment throughout the work.

The title *Surgical Anatomy* has been replaced with the broader term *Applied Anatomy*, and under this heading many important medical considerations are now discussed. In the use of descriptive terms concerning which widely different opinions prevail, the editor has sought to take a middle course, employing such designations as seem sanctioned by their usage in current medical literature.

Many illustrations have been added, largely from original drawings and preparations, and some from standard works.

The editor is gratefully indebted to his assistants, Dr. Howard Dehoney, Demonstrator of Anatomy, and Dr. Henry E. Radasch, Associate in Histology and Embryology, and Demonstrator of Visceral Anatomy; and also to Mr. Edmond J. O'Donnell, of Albany, for valuable aid in the preparation of this revision. The editor also wishes to thank Mr. William A. Hassett, of Lea & Febiger, for indexing the book, for seeing it through the press, and for the valuable aid he has ungrudgingly given.

E. A. S.

PUBLISHERS' NOTE TO EIGHTEENTH EDITION.

BOOKS, like men, have characters that can be analyzed to a certain point, but beyond or below lies a quality, subtle as life, and incapable of analysis or imitation, which is called personality. The greater the author, and the more intense his mental action in creating his book, the more it partakes of this element. This principle, so clear as to be almost axiomatic, is illustrated to the fullest extent in the work in hand. Henry Gray combined two faculties, either one sufficient to make his name famous. He was a great anatomist and a great teacher. He possessed a thorough knowledge of anatomy and an equal insight into the best methods of imparting it to other minds. His text was unequalled in clearness, and he united with it a series of incomparable illustrations. He devised the method of engraving the names of the parts directly upon them, thereby exhibiting at a glance not only their nomenclature, but also their position, extent, and relations. His work, still unique in this respect, was also the first to employ colors. Summing all, it is hardly to be wondered at that students and teachers alike find their labors reduced and the permanence of knowledge increased by the use of such a book.

On its original appearance, half a century ago, it immediately took the leading place, and it has not only maintained its position in its own subject, but has also become the best-known work in all medical literature in the English language. It is incomparably the greatest text-book in medicine, measured by the numbers of students who have used it, and it is unique also in being the one work which is certain to be carried from college to afford guidance in the basic questions underlying practice.

The consequent demand is evidenced in the number of editions, which collectively represent the labors of many of the leading anatomists since the early death of its talented author. This new revision is, perhaps, the most thorough to which Gray's work has ever been subjected. Every line has been carefully considered, any possible obscurity has been clarified, the latest accessions to anatomical knowledge have been introduced, and much has been rewritten. Care has been exercised to make the text a homogeneous, sequential, and complete presentation of the subject, sufficing for every need of the student, physician, or surgeon. By condensation and the omission of duplications it has been found possible to combine this increased aggregate of knowledge with a considerable reduction in the number of pages, to the reader's obvious advantage. The illustrations have also been revised, those which no longer represented the latest views being dropped, and a great number of new ones added.

As ample directions are given for dissecting, this volume will serve every requirement of the student throughout his course. The new nomenclature and that still in common use have been introduced in a manner rendering the work universal in the prime essential of terminology. The Table of Contents is so arranged as to give a complete conspectus of anatomy, a feature of obvious value. The whole book is thoroughly organized in its headings and the sequence of subjects, so that the student receives his knowledge of the parts in their anatomical dependence.

As a teaching instrument the new *Gray's Anatomy* embodies all that careful thought and unstinted expenditure can combine in book form.

CONTENTS.

DESCRIPTIVE AND APPLIED ANATOMY.

OSTEOLOGY.

Introduction	33	The Temporal Bone	80
GENERAL ANATOMY OF THE SKELETON.		The Squamous Portion	80
The Skeleton	35	The Petromastoid Portion	82
Number of the Bones	35	The Mastoid Portion	82
Form of Bones	35	The Petrous Portion	84
Long Bones	35	The Tympanic Portion	87
Short Bones	36	The Sphenoid Bone	89
Flat Bones	36	The Body of the Sphenoid Bone	90
Irregular Bones	36	The Greater or Temporal Wings	92
Surface of Bones	36	The Lesser or Orbital Wings	93
Structure of Bone	38	The Pterygoid Processes	94
Bloodvessels of Bone	40	The Sphenoidal Turbinated Processes	95
Chemical Composition of Bone	41	The Ethmoid Bone	96
Ossification and Growth of Bone	42	The Horizontal Lamina or Cribriform Plate	96
Intramembranous Ossification	42	The Vertical Plate	97
Intracartilaginous Ossification	43	The Lateral Mass or Labyrinth	97
Applied Anatomy of the Bones	46	<i>The Bones of the Face.</i>	
SPECIAL ANATOMY OF THE SKELETON.		The Nasal Bones	99
THE VERTEBRAL OR SPINAL COLUMN OR THE SPINE.		The Maxillæ	100
<i>General Characters of a Vertebra.</i>		Changes Produced in the Upper Jaw by Age	106
The Cervical Vertebrae	49	The Lacrimal Bone	106
Atlas	50	The Malar Bone	107
Axis	52	The Palate Bone	109
Seventh Cervical	53	The Horizontal Plate	109
The Thoracic Vertebrae	53	The Vertical or Perpendicular Plate	110
Peculiar Thoracic Vertebrae	54	The Turbinated Bone	113
The Lumbar Vertebrae	56	The Vomer	114
The Sacral and Coccygeal Vertebrae	58	The Mandible or Lower Jaw	115
Sacrum	58	The Body	115
The Sacral Canal	61	The Perpendicular Portion or Rami	117
Differences in the Sacrum of the Male and Female	61	Changes Produced in the Mandible by Age	119
Coccyx	61	Side Views of the Mandible at Different Periods of Life	119
Structure of the Vertebrae	62	The Sutures	121
Development of the Vertebrae	63	<i>The Skull as a Whole.</i>	
Development of the Atlas	63	The Vertex of the Skull	123
Development of the Axis	64	The Base of the Skull	123
Development of the Seventh Cervical	64	The Lateral Region of the Skull	132
Development of the Lumbar Vertebrae	64	The Temporal Fossa	132
The Vertebral Column as a Whole	66	The Mastoid Portion	133
Surface Form of the Vertebral Column	67	The Zygomatic Fossa	133
Applied Anatomy of the Vertebral Column	68	The Sphenomaxillary Fossa	134
THE SKULL.		The Anterior Region of the Skull	134
<i>The Cerebral Cranium.</i>		The Orbits	136
The Occipital Bone	70	The Nasal Cavity	138
The Parietal Bone	74	Development of the Skull	141
The Frontal Bone	76	Differences in the Skull Due to Age	143
Vertical Portion of the Frontal Bone	76	Obliteration of the Sutures	144
Horizontal or Orbital Portion of the Frontal Bone	79	Differences in the Skull Due to Sex	144
		Supernumerary, Wormian, Sutural or Epactal Bones	145
		Craniology	145
		Surface Form of the Skull	147
		Applied Anatomy of the Skull	149

THE HYOID OR LINGUAL BONE	153	The Phalanges of the Hand	204
THE THORAX.		Surface Form of the Bones of the Hand	205
Boundaries of the Thorax	154	Applied Anatomy of the Bones of the Hand	205
The Cavity of the Thorax	157	Development of the Bones of the Hand	206
The Sternum or Breast Bone	157		
The Ribs	161	THE LOWER EXTREMITY.	
Common Character of Ribs	162	The Os Innominatum	207
Peculiar Ribs	163	The Ilium	207
The Costal Cartilages	165	The Ischium	210
Surface Form of Thorax	166	The Pubis	212
Applied Anatomy of Thorax	167	The Cotyloid Cavity or Acetabulum	213
		The Obturator or Thyroid Foramen	214
THE UPPER EXTREMITY.		The Pelvis	215
THE Shoulder Girdle.		The False Pelvis	215
The Clavicle	169	The True Pelvis	215
Surface Form of the Clavicle	171	Position of the Pelvis	217
Applied Anatomy of the Clavicle	172	Axes of the Pelvis	218
The Scapula or Shoulder Blade	172	Differences between the Male and Female Pelvis	218
Surface Form of the Scapula	172	Surface Form of the Pelvis	219
Applied Anatomy of the Scapula	172	Applied Anatomy of the Pelvis	220
THE Arm.		THE Thigh.	
The Humerus or Arm Bone	178	The Femur or Thigh Bone	221
Surface Form of the Humerus	184	Surface Form of the Femur	228
Applied Anatomy of the Humerus	184	Applied Anatomy of the Femur	229
THE Forearm.		THE Leg.	
The Ulna or Elbow Bone	185	The Patella or Knee-cap	230
Surface Form of the Ulna	190	Surface Form of the Patella	231
The Radius	190	Applied Anatomy of the Patella	231
Surface Form of the Radius	192	The Tibia or Shin Bone	231
Applied Anatomy of the Radius and Ulna	192	Surface Form of the Tibia	236
		The Fibula or Calf Bone	236
		Surface Form of the Fibula	238
		Applied Anatomy of the Bones of the Leg	239
THE Hand.		THE Foot.	
The Carpus	195	The Tarsus	239
Common Characters of the Carpal Bones	196	The Calcaneus	239
Bones of the Upper Row	196	The Astragalus or Ankle Bone	244
The Scaphoid or Navicular Bone	196	The Cuboid	245
The Semilunar Bone	197	The Scaphoid or Navicular Bone	246
The Cuneiform Bone	197	The Cuneiform or Wedge Bones	247
The Pisiform Bone	198	The Metatarsal Bones	249
Bones of the Lower Row	198	Common Characters of the Metatarsal Bones	250
The Trapezium	198	Peculiar Characters of the Metatarsal Bones	250
The Trapezoid	199	The Phalanges of the Foot	252
The Os Magnum	199	Development of the Foot	254
The Unciform	200	Construction of the Foot as a Whole	254
The Metacarpus	201	Surface Form of the Foot	255
Common Characters of the Metacarpal Bones	201	Applied Anatomy of the Foot	256
Peculiar Characters of the Metacarpal Bones	202	Sesamoid Bones	257

THE ARTICULATIONS OR JOINTS.

Structures Composing the Joints	259	Articulations of the Vertebral Column—	
Bone	259	The Ligaments Connecting the Articular Processes	272
Cartilage	259	The Ligaments Connecting the Spinous Processes	272
Ligaments	261	The Ligaments Connecting the Transverse Processes	272
Synovial Membrane	261	Articulations of the Atlas with Axis	273
Forms of Articulation:		Articulations of the Vertebral Column with Cranium.	
Synarthrosis (Immovable Articulation)	263	Articulation of Atlas with Occipital Bone	275
Amphiarthrosis (Mixed Articulation)	264	Articulation of Axis with Occipital Bone	277
Diarthrosis (Movable Articulation)	264	Applied Anatomy of Articulations of the Vertebral Column	278
Kinds of Movement Admitted in Joints	266	The Temporomandibular Articulation	279
Ligamentous Action of Muscles	267	Surface Form	281
		Applied Anatomy	281
ARTICULATIONS OF THE TRUNK.			
Articulations of the Vertebral Column	268		
The Ligaments of the Vertebral Bodies or Centra	268		
The Ligaments Connecting the Laminae	271		

Articulations of the Ribs with the Vertebral or the Costovertebral Articulations	282	Carpometacarpal Articulations	318
The Costocentral Articulations	282	Articulation of the Metacarpal Bone of the Thumb with the Trapezium	318
The Costotransverse Articulations	284	Articulations of the Metacarpal Bones of the Four Inner Fingers with the Carpus	318
The Costosternal Articulations	286	Articulations of the Metacarpal Bones with Each Other	319
Articulations of the Cartilages of the Ribs with Each Other	288	Metacarpophalangeal Articulations	320
Articulations of the Ribs with their Cartilages	288	Surface Form	321
Articulations of the Sternum	288	Articulations of the Phalanges	321
Articulation of the Vertebral Column with the Pelvis	289		
Articulations of the Pelvis	290	ARTICULATIONS OF THE LOWER EXTREMITY.	
Articulation of the Sacrum and Ilium	290	The Hip-joint	322
Ligaments Passing between the Sacrum and Ischium	291	Surface Form	329
Articulation of the Sacrum and Coccyx	292	Applied Anatomy	329
Articulation of the Pubic Bones	294	The Knee-joint	331
		Surface Form	338
		Applied Anatomy	338
ARTICULATIONS OF THE UPPER EXTREMITY.		Tibiofibular Articulation	340
Sternoclavicular Articulation	295	Superior Tibiofibular Articulation	340
Surface Form	297	Middle Tibiofibular Ligament or Interosseous Membrane	341
Applied Anatomy	297	Inferior Tibiofibular Articulation	341
Acromioclavicular Articulation or Scapulo-clavicular Articulation	297	The Tibiotarsal Articulation or Ankle-joint	342
Surface Form	299	Surface Form of Ankle-joint	346
Applied Anatomy	299	Applied Anatomy of Ankle-joint	346
Proper Ligaments of the Scapula	299	Articulations of the Tarsus	347
The Shoulder-joint	301	Articulation of the Os Calcis and Astragaloid or the Calcaneo-astragaloid Articulation	347
Surface Form	304	Articulation of the Os Calcis with the Cuboid	347
Applied Anatomy	304	The Ligaments Connecting the Os Calcis and Scaphoid	348
The Elbow-joint	306	Applied Anatomy	349
Surface Form	309	Articulation of the Astragalus with the Scaphoid Bone	349
Applied Anatomy	309	The Articulation of the Scaphoid with the Cuneiform Bones	349
Radio-ulnar Articulation	310	The Articulation of the Scaphoid with the Cuboid	350
Superior Articulation	310	The Articulations of the Cuneiform Bones with Each Other or the Inter-cuneiform Articulations	350
Surface Form	311	The Articulation of the External Cuneiform Bone with the Cuboid	351
Applied Anatomy	311	Applied Anatomy	351
Middle Radio-ulnar Ligaments	311	Tarsometatarsal Articulations	351
Inferior Articulation	312	Articulations of the Metatarsal Bones with Each Other	352
Surface Form	314	Metatarsophalangeal Articulations	353
The Radiocarpal or Wrist-joint	314	Articulations of the Phalanges	354
Surface Form	315	Surface Form	354
Applied Anatomy	315	Applied Anatomy	354
Articulations of the Carpus	315		
Articulations of the First Row of Carpal Bones	315		
Articulations of the Second Row of Carpal Bones	316		
Articulations of the Two Rows of Carpal Bones with Each Other	316		

THE MUSCLES AND FASCIÆ.

General Description of Muscles	355	The Auricular Region—	
Structure of Striated Muscle	355	Retrahens Aures	366
Structure of the Muscle Fibre	356	The Palpebral Region	366
Form and Attachment of Muscles	357	Dissection	366

DESCRIPTIVE AND APPLIED ANATOMY.

INTRODUCTION.

ANATOMY (*ἀνά*, apart, and *τέμνω*, I cut) is the name given to that division of natural science which deals with the structure or organization of living things. Human anatomy is that division of general anatomy which applies to the structure of man, bearing in mind the fact that man is distinguished as a separate genus among primate mammals, an order of vertebrates.

Man, as a vertebrate, possesses an internal skeleton with a median longitudinal axis, which is divided transversely into segments called vertebræ. This vertebral axis (spinal column) in the habitually erect position of the human body is supported by the pelvic limbs, and is surmounted by the skull. The pelvic limbs serve the purposes of progression, while the pectoral limbs are adapted as organs of prehension; a distinction common to nearly all primates is the possession of an opposable first digit or thumb. The possession of milk glands, rudimentary in the male, but well developed and important in the female, relegates the human species to the class of mammals.

The present work is an account of the various parts and organs of the human body, being descriptive of their characteristics as revealed by dissection, and, with a view toward practical application, certain parts or regions of the body are examined in their entirety. These two methods of studying anatomy are conventionally termed *descriptive anatomy* and *applied* or *topographic anatomy*. *Embryology* deals with the origin and development of the body and its organs. *Histology* deals with the minute structure of the tissues and organs as revealed by the microscope. In the present work only brief accounts of the embryology and histology of the organs are interpolated in their proper places; the minute details must be sought for in special works upon these subjects.

The systematic consideration of the parts of the human body requires a foreword as to the descriptive terms, nomenclature, and classification employed in anatomy.

The descriptive terms are names indicative of position and direction. Despite the structural homologies discernible among vertebrates in general, there are wide differences regarding the natural attitude or position habitually assumed, so that whatever is situated "in front" in the erect man is "below" in the quadrupedal animal. The use of terms like anterior, posterior, superior, inferior, in front of, beneath, has given rise to great ambiguity and confusion whenever applied at one and the same time to homologous parts in man and other vertebrates.

It is essential that the names used in designating structural parts shall be so definite that each of the terms shall have but one signification. The study of anatomy has been made unnecessarily difficult by a multiplicity of synonyms and compound names, when single words would answer all requirements. Furthermore, many of the terms even now in general use are not equally applicable to lower animals and man, a condition which constitutes a great hindrance to anatomic progress. Various reforms have been proposed, chief of which has been that of a commission of the German Anatomic Society, which, in 1895, formulated a list of terms, the *Bâsle Nomina Anatomica* (BNA), which is unfortunately

replete with serious imperfections and inconsistencies. Thus while one of the branches of the radial nerve is called the *N. cutaneus brachii posterior*, the nominal suffix of two other branches of the same nerve is *dorsalis*. It cannot be said that the BNA has as yet completely displaced some of the designations in common use to that degree which its enthusiastic advocates would wish. The ambiguous, confusing, and vague terms will gradually fall into disuse as time shows their inutility and better expressions achieve universal adoption.

For descriptive purposes the human body is supposed to be in the erect position, the arms hanging by the sides and the palms of the hands directed forward. The body, as a whole, as with most vertebrates, consists of two general divisions, *axial* and *appendicular*; the former is the body proper (*soma*), the latter comprises the limbs (*membra*). The middle plane of the body is called the *meson*, from the Greek *το μέσον*, the middle; while *mesal* and *mesad* (*ad* being the Latin equivalent of the English -ward) are adjectival and adverbial inflections. The mesal plane is also the dorsoventral plane which passes approximately through the sagittal suture of the skull, and hence any plane parallel to it is termed a *sagittal plane*. A vertical plane at right angles to the mesal plane passes, roughly speaking, through the central part of the coronal suture or through a line parallel to it; such a plane is therefore called a *coronal plane* or *frontal plane*. A plane at right angles to both the mesal and coronal planes is termed a *transverse plane*. The terms *anterior* and *posterior* have been employed to indicate the relation of parts to the front or back of the body, and the terms *superior* and *inferior* to signify the relative levels of different structures; but the growing use of data derived from comparative anatomy and embryology in the elucidation of the human structure makes it desirable that terms should be employed which may without ambiguity indicate relative position in both man and animals. Thus, *ventral* and *dorsal*, *cephalic* and *caudal* (together with their adverbial derivatives ending in *-ad*), are preferable and are thus sometimes used in this edition. *Lateral* and *laterad* are general terms pertaining to the sides of the body, while *dextral* and *sinistral* are specific terms for right and left respectively. The terms *central* (*centrad*) and *peripheral* (*peripherad*) are in general use, though specially applicable to the bloodvessels and the nerve system. The common terms "inner" and "outer," "deep" and "superficial," "beneath," "under," and so on, are too frequently ambiguous. The use of the words *ental* and *ectal*, derived respectively from *ἐντός* (inward) and *ἐξτός* (outward), and their inflections *entad* and *ectad* often serve to avoid such ambiguity. Wherever a series of organs embraces several similar parts, bearing like names, the general terms are combined with distinctive prefixes, as, for instance, *supraspinatus* and *infraspinatus*. The terms *proximal* and *distal* refer to the attached and free ends of the limbs and their parts, being preferable to the less precise and sometimes confusing designations of upper and lower. The other aspects (borders or sides) of each limb are variously designated by the terms *ulnar*, *radial*, *anconal*, and *thenar*; *tibial*, *fibular*, *patellar*, and *popliteal*. It is often convenient to speak of the *flexor* and *extensor aspects* of the limb divisions and their bones. The designation of parts in the limbs by anterior and posterior is still largely employed, though the demands of consistency and logic will probably compel the adoption of substitutes more in accord with the nomenclature of comparative anatomy. The classification which is used in the present work is as follows:

Osteology, or description of the bones.

Syndesmology, or description of the ligaments.

Myology, or description of the muscles and fasciæ.

Angiology, or description of the heart and the bloodvessels and lymph vessels.

Neurology, or description of the nerve system and organs of special sense.

Splanchnology, or description of the viscera, comprising the organs of respiration and phonation, digestion, reproduction, excretion, and internal secretion.

OSTEOLOGY.

GENERAL ANATOMY OF THE SKELETON.

THE general framework of the body is built up mainly of a series of bones, supplemented, however, in certain regions by pieces of cartilage; the bony part of the framework constitutes the *skeleton*.

In comparative anatomy the term skeleton has a wider application, as in some of the lower animals hard, protective, and supporting structures are more extensively distributed, being developed in association with the integumentary system. In such animals the skeleton may be described as consisting of an internal or deep skeleton, the *endoskeleton*, and an external or superficial, the *exoskeleton*. In the human subject the exoskeleton is extremely rudimentary, its only important representatives being the teeth and nails. The term skeleton is, therefore, confined to the endoskeleton, and this is divisible into an *axial* part, which includes that of the head and trunk, and an *appendicular* part, which comprises that of the limbs.

In the skeleton of the adult there are 206 distinct bones, as follows:

Axial Skeleton	{	Vertebral column	26	
		Skull	22	
		Hyoid bone	1	
		Ribs and sternum	25	
			—	74
Appendicular Skeleton	{	Upper limbs	64	
		Lower limbs	62	
			—	126
Auditory ossicles				6
Total				206

The patellæ are included in this enumeration, but the smaller sesamoid bones are not reckoned.

Bones are divisible, according to their shape, into four classes—*long*, *short*, *flat*, and *irregular*.

Long Bones.—The long bones are found in the limbs, where they form a system of levers, which sustain the weight of the trunk and confer the power of locomotion and prehension. A long bone consists of a shaft and two extremities. The *shaft*, or *diaphysis*, is a hollow cylinder, the central cavity being termed the *medullary canal*; the wall consists of dense, compact tissue of considerable thickness in the middle part of the shaft, but becoming thinner toward the extremities; the cancellous tissue is scanty. The *extremities*, or *epiphyses*, are generally expanded, for the purposes of articulation and to afford broad surfaces for muscle attachment. They are usually developed from separate centres of ossification termed *epiphyses*, and consist of cancellous tissue surrounded by a thin layer of compact bone. The long bones are not straight, but curved, the curve generally taking place in two planes, thus affording greater strength to the bone. The

bones belonging to this class are the **clavicle, humerus, radius, ulna, femur, tibia, fibula, metacarpal** and **metatarsal** bones, and the **phalanges**.

Short Bones.—Where a part of the skeleton is intended for strength and compactness, and its motion is at the same time slight and limited, it is divided into a number of small bones united by ligaments, and the separate bones are short and compressed, such as the bones of the **carpus** and **tarsus**. These consist of cancellous tissue covered by a thin crust of compact substance. The **patellæ** also, together with the other sesamoid bones, are by some regarded as short bones.

FIG. 1.—General view of the human skeleton.

Flat Bones.—Where the principal requirement is either extensive protection or the provision of broad surfaces for the attachment of muscles, we find the osseous structure expanded into broad, flat plates, as is seen in the bones of the skull and the scapulæ. Flat bones are composed of two thin layers of compact tissue enclosing between them a variable quantity of cancellous tissue. In the cranial bones these layers of compact tissue are familiarly known as the **tables of the skull**; the outer table is thick and tough; the inner table is thinner, denser, and more brittle, and hence is termed the **vitreous table**. The intervening cancellous tissue is called the **diploë**. The flat bones are: the **occipital, parietal, frontal, nasal, lacrimal, vomer, scapula, os innominatum, sternum, ribs**, and, according to some, the **patella**.

Irregular Bones.—The irregular or mixed bones are such as, from their peculiar form, cannot be grouped under either of the preceding heads. Their structure is similar to that of other bones, consisting of a layer of compact tissue externally and of spongy, cancellous tissue within. The irregular bones are: the **vertebræ, sacrum, coccyx, temporal, sphenoid, ethmoid, malar, maxilla, mandible, palate, turbinated, and hyoid**.

Surfaces of Bones.—If the surface of any bone is examined, certain eminences and depressions are seen, to which descriptive anatomists have given the following names.

These eminences and depressions are of two kinds: **articular** and **nonarticular**. Well-marked examples of *articular eminences* are found in the heads of the humerus and femur, and of *articular depressions* in the glenoid cavity of the scapula and the acetabulum. Nonarticular eminences are designated according to their form. Thus a broad, rough, uneven elevation is called a **tuberosity**; a small, rough prominence, a **tubercle**; a sharp, slender, pointed eminence, a **spine**; a narrow, rough elevation, running some way along the surface, a **ridge, line, or crest**.

The nonarticular depressions are also of very variable form, and are described as *fossæ*, *grooves*, *furrows*, *fissures*, *notches*, *sulci*, etc. These nonarticular eminences and depressions serve to increase the extent of surface for the attachment of ligaments and muscles, and are usually well marked in proportion to the muscularity of the subject; the grooves, fissures, and notches often transmit vessels and nerves.

FIG. 2.—Diagram of the structure of compact bone. A small part of a transverse section of the shaft of a long bone is shown. At the uppermost part is the periosteum covering the outside of the bone; at the lowermost part is the endosteum lining the marrow cavity. Between these is the compact tissue, consisting largely of a series of Haversian systems, each being circular in outline and perforated by a central canal. In the first one is shown only the area occupied by a system; in the second is seen the concentric arrangement of the lamellæ; and in the others, respectively, canaliculi; lacunæ; and canaliculi; the contents of the canal, artery, vein, lymphatic and areolar tissue; lamellæ; lacunæ; and canaliculi; and finally, all of the structures composing a complete system. Between the systems are circumferential and intermediate lamellæ, only a few of which are represented as lodging lacunæ, though it is to be understood that the lacunæ are in all parts. The periosteum is seen to be made up of a fibrous layer and a vascular layer, and to have upon its attached surface a stratum of cells. From the fibrous layer project inward the rivet-like fibres of Sharpey. (F. H. Gerrish.)

A prominent process projecting from the surface of a bone which it has never been separate from or movable upon is termed an **apophysis** (from ἀπόφυσις, an excrescence); but if such process is developed as a separate piece from the rest of the bone, to which it is afterward joined, it is termed an **epiphysis** (from ἐπιφυσις, an accretion). The main part of the bone, or shaft, which is formed from the primary centre of ossification, is termed the **diaphysis**, and is separated, during growth, from the epiphysis by a layer of cartilage, at which growth in length of the bone takes place. Some bones are hollow and contain **sinuses**,

which are spaces for air. **Canals**, or **foramina**, are channels or openings in bone through which nerves or vessels pass.

Structure of Bone.—Bone is a highly specialized form of connective tissue. In reality, it is white fibrous tissue, calcified and structurally modified until it becomes osseous tissue. Bone is not simply a crude mass resulting from the calcification of cartilage or fibrous tissue; it is a distinct tissue, of a definite structure, the constituent parts of which are arranged symmetrically.

There are two varieties of bone: **dense or compact bone** (*substantia compacta*), and **cancellous, loose, or spongy bone** (*substantia spongiosa*).

Compact bone is dense, and is always found upon the exterior of the bony tissue. Even this apparently compact tissue is porous; it differs from cancellous bone in its greater density and in the arrangement of its osseous substance into lamellæ. It forms practically the entire shafts of the long bones and constitutes the outer portion of their extremities and of the short, flat, and irregular bones. With the exception of enamel and dentin it represents the hardest substance of the body, is tough and elastic, and much force is required to break it. Compact bone consists of an outer membrane, the **periosteum**, internal to which is seen the **osseous tissue**.

FIG. 3.—Fibres of Sharpey from the parietal bone (adult man) isolated by dissociation. (After Kölliker.)

Sharpey's fibres (Fig. 3), which penetrate the bone at right angles to its surface, and carry bloodvessels. They do not directly enter the Haversian systems, but only the circumferential and intermediate lamellæ—parts that are formed by periosteal action. Prolongations from some of these vessels reach the Haversian canals, and even the bone marrow. In the extremities of

The **periosteum** (Fig. 2) is a fibrous membrane adhering to the surface of the bone in nearly every part except at the cartilage-covered extremities. When strong tendons or ligaments are attached to the bone, the periosteum is incorporated with them. By means of the periosteum many vessels reach and enter the hard bone through Volkmann's canals. This is shown by stripping the periosteum from the surface of living bone, when small bleeding points are seen, each of which marks the entrance of a vessel from the periosteum. It thus becomes obvious that the loosening of the periosteum, by depriving a portion of the bone of its nourishment, may produce necrosis. The membrane is firmly attached to the bone by trabeculæ of fibrous tissue,

FIG. 4.—Transverse section of compact tissue of bone. Magnified about 150 diameters. (Sharpey.)

a long bone, vessels from the periosteum penetrate the layer of compact bone and reach the cancellous tissue. In the newborn and in the young the periosteum is composed of three layers: an **outer or fibrous layer**, containing some bloodvessels, and composed of bundles of white fibrous tissue; a **middle or fibroelastic layer**, containing some bloodvessels, fibrous tissue, and much elastic tissue; and an **inner or osteogenetic layer**, which is very vascular and contains numerous cells, which are converted into osteoblasts or bone-forming cells.

Transverse Section of Compact Bone (Fig. 4).—The osseous tissue consists of cells, osteoblasts, and intercellular substance arranged in lamellæ. In the osseous tissue are found Haversian systems, lacunæ, canaliculi, and osteoblasts. In the middle of long bones is a space, the marrow cavity, containing the marrow.

There are four varieties of lamellæ: (1) The periosteal, peripheral, circumferential, or external; (2) the Haversian, or concentric; (3) the interstitial, ground, or intermediate; and (4) the perimedullary, or internal. The periosteal lamellæ are sometimes called primary, as they are the first to appear, and are formed by the direct transformation of the inner layer of the periosteum into bone. In the shaft of a long bone there are several layers of periosteal lamellæ, but no one layer is extensive enough to surround the bone completely. Lacunæ and canaliculi are present.

In the outer surface of the layer of periosteal lamellæ depressions exist that are known as Howship's foveolæ, or lacunæ. These depressions are made by large cells, called osteoclasts, which destroy bone. There are no Haversian canals in this outer layer, but there are some large channels, Volkmann's canals, that convey bloodvessels into the bone and run at right angles to the periosteal surface. Many small arteries from the periosteum enter the periphery both of the shaft and of the epiphyses.

The Haversian or concentric lamellæ are circular layers arranged around a central space, or canal, known as the Haversian canal. There is no fixed number of these layers, there being usually from five to ten. The layers of each system are parallel to one another,

FIG. 5.—Nucleated bone cells and their processes, contained in the bone lacunæ and their canaliculi respectively. From a section through the vertebra of an adult mouse. (Klein and Noble Smith.)

FIG. 6.—Combined transverse and longitudinal section of compact bone. CH, Longitudinal Haversian canal and anastomosing canals. o, Communicating with medullary cavity. Si, Intermediate systems. Spe, Circumferential lamellæ. Spi, Perimedullary lamellæ. os, Osteoblasts. (Poirier and Charpy.)

but the layers of different systems cross at various angles. Between these layers are small, irregular spaces called lacunæ; and extending radially out from the lacunæ and piercing the various lamellæ are delicate canals known as canaliculi, which connect the lacunæ. The lacuna nearest to the Haversian canal communicates with it by means of canaliculi; and canaliculi also communicate with other Haversian systems. The Haversian canal contains bloodvessels—an artery or a vein, or both—and a nerve. The vessel in the canal is covered with endothelial cells, and the canal itself is lined with them. The space thus formed is a lymph channel, and into these channels the canaliculi empty. Beneath the periosteum and at the periphery of the medullary cavity there are lymph spaces that are in direct communication with the canaliculi of the Haversian systems. In each lacuna is a bone cell—a corpuscle that almost fills the space, and sends arms, or processes, out into the canaliculi (Fig. 5). This bone cell is an osteoblast.

The interstitial or intermediate lamellæ occupy the spaces between the Haversian systems. They represent the remains of peripheral lamellæ. They are usually short and very irregular, but possess lacunæ and canaliculi, which are arranged as in the Haversian systems.

The perimedullary lamellæ are irregular and few in number. They surround the marrow cavity, and in areas may be interrupted. Lacunæ, canaliculi, and osteoblasts are present.

Lining the marrow cavity surface of the bone is a membrane, the endosteum, that resembles the periosteum in structure, but is not quite so prominent.

The osteoblasts are irregular, flattened, stellate masses of protoplasm, possessing a number of processes. The protoplasm is granular, and each cell contains a large and distinct nucleus.

Osteoblasts are met with in the deeper layer of the periosteum, in the endosteum, and in the lacunæ.

Longitudinal Section of Compact Bone (Figs. 6 and 8).—We do not see concentric rings, as in a transverse section, but rows of lacunæ parallel to the course of the Haversian canals—and these canals appear like half tubes instead of circular spaces. The tubes are seen to branch and communicate, so that each separate Haversian canal runs only a short distance. In other respects the structure closely resembles that of a transverse section.

Cancellous bone is found in the interior of flat and irregular bones, forming the bulk of the extremities of the long bones. It consists of anastomosing spicules of bone from a meshwork for red marrow. The spicules have a fibrillar structure, and contain lacunæ and canaliculi, but no Haversian systems.

In the epiphyses the spicules are placed, as a rule, at right angles to the planes of the articular surface (the lines of greatest pressure); these are bound together by other spicules that correspond in direction to the planes of the articulation (the lines of greatest tension). Those spicules nearer the marrow cavity are usually heavier and stronger.

FIG. 7.—Cells of red marrow of the guinea-pig. a-d. Myeloplasmic masses. e-l. Marrow cells proper. j-l. Erythroblasts, some in process of division. (Schäfer.)

Marrow.—There are three varieties: **red**, **yellow**, and **mucoid**.

Red marrow (*medulla ossium rubra*) is found in the diploë of the cranial bones, in the cancellous tissue of the vertebræ, ribs, and sternum, and in the extremities of the long bones. Red marrow contains much less fat and is less solid than yellow marrow. It consists of a delicate network of retiform connective tissue, supporting a dense capillary plexus; some fat; and numerous cellular elements. Surrounding the marrow is the **endosteum**. The cellular elements of red marrow (Figs. 7 and 12) comprise four main groups: (1) **Marrow cells**, or **myelocytes**, which are granular protoplasmic masses, capable of ameboid movements, and containing large nuclei. They are not found in normal blood, but are abundant in leukemia. (2) Small nucleated, reddish cells called **erythroblasts** are found; they resemble the nucleated red cells of the blood of the embryo; eventually by the loss of their nuclei they become normal red blood corpuscles. (3) Nonnucleated red blood corpuscles; and (4) giant cells, containing one or more nuclei—the **osteoclasts**—complete the cellular elements. In addition there are a large number of **leukocytes**, or white blood cells, i. e., *polynuclear cells*, *eosinophiles*, and *basophiles*.

Yellow marrow is found in the shafts of long bones of adults, and differs from the preceding in the presence of a great quantity of fat and a corresponding decrease in the number of cellular elements.

Gelatinous or mucoid marrow is formed by the absorption of the fat and the cellular elements of yellow marrow, and by the serous infiltration of the intercellular substance. It is produced by starvation, old age, and certain pathological conditions. Neither yellow nor mucoid marrow are blood-cell forming in function.

Bloodvessels of Bone.—Small arteries derived from the periosteum enter Volkmann's canals and pass to the Haversian canals and ultimately to the marrow. The cancellous tissue is supplied by fewer but larger vessels, which are derived from the periosteum, and which often penetrate the covering of the compact bone and ramify in the cavities of the spongy tissue.

The marrow is supplied by a large artery (sometimes more than one) called the **nutrient artery**. It enters the bone by the nutrient foramen, which is usually near the centre of the shaft, runs in an oblique canal through the compact substance, giving off branches to this

structure, and entering the medullary cavity, sends branches toward the extremities, thus forming capillary plexuses in the marrow. These branches communicate with branches from the periosteal vessels. The walls of the vessels are very thin; the venous blood enters the spaces of the red marrow, and the current becomes extremely slow. Small veins collect the venous blood and emerge from the bone.

FIG. 8.—From a ground longitudinal section through the diaphysis of the human ulna. All canals are filled with pigment, which is here black. Haversian canals are cut longitudinally. $\times 90$. (Szymonowicz.)

Veins emerge from the long bones in three places: (1) One or two large veins accompany the nutrient artery. (2) Numerous veins emerge at the articular extremities. (3) Many small veins arise in and emerge from compact substance. The latter two classes do not accompany arteries. The veins in the marrow and in the bone are devoid of valves; but immediately after emerging from the bone they have numerous valves. In the flat cranial bones the veins are numerous and large.

The **lymphatics** are chiefly periosteal; but some have been demonstrated as entering the bone, along with the vessels, and running in the Haversian canals.

Nerves, medullated (*myelinic*) and nonmedullated (*amyelinic*), are found in bone. They are distributed freely to the periosteum, and some of the fibres terminate in this structure as Pacinian corpuscles. Nerves accompany the nutrient arteries into the interior of the bone, and also reach the marrow from the periosteum by way of Volkmann's canals and the Haversian canals. They certainly supply the arterial coats and possibly ramify about the osteoblasts. Nerves are most numerous in the articular extremities of the long bones, in the vertebræ, and the large flat bones.

Chemical Composition of Bone.—Bone consists of about 64 per cent. of *animal (organic)* and about 36 per cent. of *earthy (inorganic)* substance intimately combined.

The *animal* part may be obtained by immersing the bone for a considerable time in dilute mineral acid, after which process the bone comes out exactly the same shape as before, but perfectly flexible, so that a long bone (one of the ribs, for example) can easily be tied into a knot. If now a transverse section is made, the same general arrangement of the Haversian canals,

lamellæ, lacunæ, and canaliculi is seen, though not so plainly as in the ordinary section. The animal basis is largely composed of **ossein**, or **fat collagen**. When boiled with water, especially under pressure, fat collagen is almost entirely resolved into gelatin.

The *earthy* part may be obtained by calcination, in which process the animal matter is completely burned out. The bone will still retain its original form, but it will be white and brittle, will have lost about one-third of its original weight, and will crumble upon the slightest pressure. The earthy matter confers on bone its hardness and rigidity, and the animal matter its tenacity. The mineral matter consists chiefly of calcium phosphate, forming about two-thirds of the weight of bone.

Ossification and Growth of Bone.—For the early development of the skeleton the reader is referred to text-books on embryology. Embryonic connective-tissue cells of the meso-

blast develop membrane. Membrane may become bone directly or cartilage may be deposited, which cartilage by the process of ossification is changed into bone. The tissue which is eventually to become bone contains cellular elements which evolve into **osteoblasts**, or bone-forming cells. Osteoblasts exist in the connective tissues which become bone by intramembranous ossification, and in the deeper layers of the tissue called perichondrium which invests cartilage and which becomes the osteogenetic layer of the periosteum. In view of the fact that in the fetal skeleton some bones are preceded by membrane (parietal bones, frontal bone, upper part of tabular portion of occipital bone, most of the bones of the face), and others are preceded by rods of cartilage (the long bones), two kinds of ossification are described—viz., the **intramembranous** and the **intracartilaginous**.

Intramembranous Ossification.—In the case of bones which are developed in membrane no cartilaginous mould precedes the appearance of the bone tissue. The membrane, which occupies the place of the future bone, consists of white, fibrous connective tissue, and ultimately forms the periosteum. At this stage it is seen to be composed of fibres and granular cells in a matrix.

FIG. 9.—Schematic diagram, showing epiphysis and diaphysis and line of ossification. *Ep.* Epiphysis of endochondral bone. *zpt.* Zone of proliferation. *zc.* Zone of calcification. *ca.* Cartilage. (Poirier and Charpy.)

The outer portion is more fibrous, while internally the cells or osteoblasts predominate; the whole tissue is quite vascular. At the outset of the process of bone formation a little network of bony spicules is first noticed radiating from the point or centre of ossification. When these rays of

FIG. 10.—Part of the growing edge of the developing parietal bone of a fetal cat. (After J. Lawrence.)

growing bone are examined with a microscope they are found to consist at their growing point of a network of fine, clear fibres and granular corpuscles, with an intervening ground substance (Fig. 10). The fibres are termed **osteogenetic fibres**, and are made up of fine fibrils differing

little from those of white fibrous tissue. Like them, they are probably deposited in the matrix through the influence of the cells—in this case the osteoblasts. The osteogenetic fibres soon assume a dark and granular appearance from the deposition of calcareous granules in the fibres and in the intervening matrix, and as they calcify they are found to enclose some of the granular

FIG. 11.—Longitudinal section through the second phalanx of the finger of a seven months' human embryo. Stained in hematoxylin and eosin. $\times 104$. A. Periosteum. B. Primary areola. C. Periosteal bone. D. Secondary areola and marrow. E. Calcareous material. F. Endochondral bone. (Szymonowicz.)

corpuscles, or osteoblasts. By the fusion of the calcareous granules the bony tissue again assumes a more transparent appearance, but the fibres are no longer so distinctly seen. The involved osteoblasts form the corpuscles of the future bone, the spaces in which they are enclosed constituting the lacunæ. As the osteogenetic fibres grow out to the periphery they continue to ossify and give rise to fresh bone spicules. Thus, a network of bone is formed, the meshes of

FIG. 12.—Section through the red bone marrow of a rabbit. Biondi's stain. $\times 640$. A. Myelocytes. B. Eosinophiles. C. Nucleated red blood corpuscles. D. Giant cells. E. Myelocyte. (Szymonowicz.)

which contain the bloodvessels and a delicate connective tissue crowded with osteoblasts. The bony trabeculæ thicken by the addition of fresh layers of bone formed by the osteoblasts on their surface, and the meshes are correspondingly encroached upon. Subsequently successive layers of bony tissue are deposited under the periosteum and around the larger vascular channels,

which become the Haversian canals, so that the bone increases much in thickness. The process spreads laterally to the region of the future suture, and here between the various bones a layer of fibrous tissue, the **cambium layer**, is maintained until the full size of the bone is reached. The cambium layer then ossifies and the bone ceases to grow at its edges.

Intracartilaginous Ossification.—Just before ossification begins the bone is entirely cartilaginous, and in the long bone, which may be taken as an example, the process commences in the centre and proceeds toward the extremities, which for some time remain cartilaginous. Subsequently a similar process commences in one or more places in those extremities and gradually ossifies them. The extremities do not, however, become joined to the shaft by bony tissue until growth has ceased, but are attached to it by a layer of cartilaginous tissue termed the **epiphyseal cartilage**.

The first step (*proliferation*) in the ossification of the cartilage is that the cartilage cells, at the point where ossification is commencing and which is termed a **centre of ossification**, multiply, enlarge, and arrange themselves in rows (Fig. 11). The matrix in which they are embedded

FIG. 13.—Cross-section of a developing bone of a human fetus of four months. a. Periosteum. b. Boundary between endochondral and periosteal bone. c. Perichondral bone. d. increases in quantity, so that the cells become further separated from each other. A deposit of calcareous material (*calcification*) now takes place in this matrix, between the rows of cells, so that they become separated from each other by longitudinal columns of calcified matrix. These columns are connected to one another by transverse bars of calcareous substance, and present a granular and opaque appearance. In the calcareous areas the cartilage cells reproduce so rapidly that a number of cells are seen in each large lacuna, or space, which is called a **primary areola**. This process is succeeded by destruction of some of the columns between the smaller spaces, forming thus a fewer number of larger spaces, the **secondary areolæ**. Some of the cells within the areolæ disappear, others become osteoblasts, which apply themselves to the columns and secrete a thin veneer of osseous tissue upon the calcareous matter; still others of these cells become osteoclasts.

At the same time that this process is going on in the centre of the solid bar of cartilage of which the fetal bone consists, certain changes are taking place on its surface. This is covered by a very vascular membrane, the **perichondrium**, entirely similar to the embryonic connective tissue already described as constituting the basis of membrane bone, on the inner or cartilage

surface of which the cells become **osteoblasts**, or bone-forming cells. By the agency of these cells a thin layer of bony tissue is being formed between the outer membrane, now the **periosteum**, and the cartilage by the *intramembranous* mode of ossification just described; this constitutes the first periosteal lamella. These two processes go on simultaneously. The second stage (*vascularization*) consists in the prolongation into the cartilage of processes of the deeper or osteogenetic layer of the periosteum, these processes consisting of bloodvessels and cells—**osteoblasts**, or **bone formers**, and **osteoclasts**, or **bone destroyers**. The latter are similar to the giant cells (myeloplakes) found in marrow, and they excavate passages through the newly formed bony layer by absorption, and pass through it into the areolæ. Wherever these processes come in contact with the calcified walls of the primary areolæ they absorb it, and thus cause a fusion of the original cavities and assist in the formation of larger spaces, which are termed the **secondary areolæ** (Sharpey), or **medullary spaces**. These secondary spaces become filled with embryonic marrow, consisting of osteoblasts, vessels, a few leukocytes, and a few myelocytes.

The first periosteal lamella is rapidly followed by the formation of others of the same nature, the osteoblasts secreting the lamellæ remaining between the successive layers with their processes passing from one to the other. The spaces occupied by these cells are the **lacunæ** and the small channels occupied by the processes are the **canaliculi**. A periosteal lamella is not smooth and regular and does not extend completely around the developing bone, but meets others that aid in completing the circle. The irregularities are due to projecting processes of bone that meet others and enclose small, irregular, longitudinal canals, which contain vessels and primitive marrow, and are the **primitive Haversian canals**. These are also seen at the junctions of the lamellæ (Fig. 13). The osteoclasts of the primitive marrow apply themselves to the walls of the canals and absorb the osseous tissue until a comparatively large and regular canal is formed, and within this canal the osteoblasts secrete successive concentric layers of bone until a small central canal alone remains which contains a little marrow and the vessels. This canal is the true **Haversian canal**. The concentric lamellæ are the Haversian lamellæ, between which the osteoblasts remain in their **lacunæ** and radiating **canaliculi**. The remains of the periosteal lamellæ between the Haversian systems constitute the **interstitial lamellæ** (Fig. 6). Within the centre

FIG. 14.—Osteoblasts from the parietal bone of a human embryo thirteen weeks old. *a*. Bony septa with the cells of the lacunæ. *b*. Layers of osteoblasts. *c*. The latter in transition to bone corpuscles. (After Gegenbauer.)

of the rod of developing bone the osteoclasts meanwhile destroy the trabeculæ of calcific material covered by osseous tissue, and thus is formed one common cavity—the *beginning of the medullary cavity*. The marrow then forms one common mass in the centre of the bone, and the surrounding fibrous tissue becomes a second periosteum, or **endosteum**, which surrounds the marrow and secretes incomplete lamellæ, thus bounding the marrow cavity as the **perimedullary lamellæ**. All of the above osseous tissue is merely temporary in the growth of the bone thickness. As can now be readily seen, the long bones increase evenly in thickness by the periosteal method, while increase in length is due entirely to the intracartilaginous method.

Such are the changes which may be observed at one particular point, the centre of ossification. While they have been going on here a similar process has been set up in the surrounding parts and has been gradually proceeding toward the ends of the shaft, so that in the ossifying bone all the changes described above may be seen in different parts, from the true bone in the centre of the shaft to the hyaline cartilage at the extremities. The bone thus formed differs from the bone of the adult in being more spongy and less regularly lamellated.

As more and more bone is removed by this process of absorption from the interior of the bone to form the medullary canal, so more and more bone is deposited on the exterior by the periosteum, until at length the bone has attained the shape and size which it is destined to retain during adult life. As the ossification of the cartilaginous shaft extends toward the articular ends it carries with it, as it were, a layer of cartilage, or the cartilage grows as it ossifies, and thus the bone is increased in length. During this period of growth the articular end, or *epiphysis*, remains for some time entirely cartilaginous; then a bony centre appears in it, and it undergoes the same process of intracartilaginous ossification; the cancellous bone of the extremities of the processes of the bones is never completely removed to form a single marrow cavity, but the

spaces become somewhat enlarged as the bones grow. The epiphyses remain separated from the shaft by a narrow cartilaginous (*cambium*) layer for a definite time (Fig. 9). This layer ultimately ossifies, the distinction between shaft and epiphysis is obliterated, and the bone assumes its completed form and shape. The same remarks also apply to the processes of bone which are separately ossified, such as the trochanters of the femur. The bones, having been formed, continue to grow until the body has acquired its full stature.

The number of ossific centres varies in different bones. In most of the short bones ossification commences at a single point in the centre, and proceeds toward the circumference. In the long bones there is a central point of ossification for the shaft or diaphysis; and one or more for each extremity, the epiphysis. That for the shaft is the first to appear. The union of the epiphyses with the shaft takes place in the reverse order to that in which their ossification began, with the exception of the fibula, and appears to be regulated by the direction of the nutrient artery of the bone. Thus, the nutrient arteries of the bones of the arm and forearm are directed toward the elbow, and the epiphyses of the bones forming this joint become united to the shaft before those at the shoulder and wrist. In the lower limb, on the other hand, the nutrient arteries pass in a direction from the knee; that is, upward in the femur, downward in the tibia and fibula; and in them it is observed that the upper epiphysis of the femur and the lower epiphysis of the tibia and fibula become first united to the shaft.

Where there is only one epiphysis, the nutrient artery is directed toward that end of the bone where there is no additional centre, as toward the acromial end of the clavicle, toward the distal end of the metacarpal bone of the thumb and great toe, and toward the proximal end of the other metacarpal and metatarsal bones.

Besides these epiphyses for the articular ends, there are others for projecting parts or processes, which are formed separately from the bulk of the bone. For an account of these the reader is referred to the description of the individual bones in the sequel.

A knowledge of the exact periods when the epiphyses become joined to the shaft is often of great importance in medicolegal inquiries. It also aids the surgeon in the diagnosis of many of the injuries to which the joints are liable; for it not infrequently happens that on the application of severe force to a joint the epiphysis becomes separated from the shaft, and such an injury may be mistaken for a fracture or dislocation.

Applied Anatomy.—It has been stated above that the bones increase first *in length* by ossification continuing to extend in the epiphyseal cartilage, which goes on growing in advance of the ossifying process; and secondly *in circumference* by deposition of new bone from the deeper layer of the periosteum. A thorough realization of these facts is essential to the student, when he comes to consider the various pathological changes which affect bone. Anything which interferes with the growth at the epiphyseal line will lead to a diminution in the length which the bone should attain in adult life, and similarly anything which interferes with the growth from the deeper layer of the periosteum will result in a disproportion in the thickness of the bone. Thus, separation of the epiphyses, septic or tuberculous disease about the epiphyseal line, and excisions involving the epiphyseal line, will result in varying amounts of shortening of the bone, as compared with that of the opposite side; whereas separation or imperfect nutrition of the periosteum results in defective growth in circumference.

It is thus obvious that a careful study of osseous development is of the very greatest utility in the proper understanding of bone disease; and, moreover, that an accurate knowledge of the blood supply of a long bone has many important bearings. The outer portion of the compact tissue being supplied by periosteal vessels, which reach the bone through muscle attachments, it follows that where the muscles or muscle attachments are well developed, and therefore amply supplied with blood, the periosteum will also be well nourished and the bones proportionately well developed in girth; this is well seen in strong, muscular men with well-marked ridges on the bones. Conversely, if the muscle development be poor, the bones are correspondingly thin and light, and if from any cause a limb has been paralyzed from early childhood, all of the bones of that extremity are remarkable for their extreme thinness—that is to say, the periosteal blood supply has been insufficient to nourish that membrane, and consequently very little new osseous tissue has been added to the bones from the outside.

The best example of this condition is seen in connection with the disease known as *infantile paralysis*, where a limb becomes paralyzed at a very early period of childhood, where the muscles become flaccid and atonic, and where the blood supply is in consequence very greatly diminished. In such cases, although the limb does continue to grow in length from the epiphyseal lines, its length is considerably less than on the normal side, as a result of the imperfect nutrition; but the most striking feature about all the long bones of the limb is their remarkable tenuity, little or no addition having been made to their diameters.

In cases where the periosteum has been separated from the compact tissue by extensive injury or inflammatory exudation, necrosis or death of the underlying portion of bone takes place, due to interference with the blood supply, and the dead portion or *sequestrum* has to be subsequently separated and cast off.

Cases, however, occur in which the inflammatory process affects the whole or a great portion

of the diaphysis of a long bone, and here extensive necrosis of the affected portion takes place, and the condition goes by the name of *acute infective periostitis*. Where this occurs the shaft of the bone dies very rapidly, especially if the singly nutrient artery be thrombosed at the same time. The pus which has formed beneath the periosteum is set free by timely excision, or burrows to the surface; the periosteum then falls back on the necrosed diaphysis and rapidly forms a layer of new periosteal bone, surrounding the sequestrum. This layer is called the *involucrum* and the openings in it through which the pus escapes the *cloacæ*. When the inflammatory process affects mainly the medullary canal, the condition is spoken of as *osteomyelitis*, and the two conditions very frequently co-exist, and then go by the name of *acute infective necrosis of bone* or *acute diaphysitis*. When the medullary cavity is filled with pus, septic thrombosis of the veins in the Haversian canals takes place, and there is a very great danger of septic emboli being separated and carried into the general circulation, thus setting up a fatal *pyemia*. In fact, *pyemia* is more frequently due to septic bone conditions than to any other cause.

In the preantiseptic days *pyemia* frequently resulted from amputations, when the medullary canal of a long bone was opened by the saw cut. *Osteomyelitis* ensued, and if the patient survived, a tubular sequestrum of the divided shaft subsequently separated.

A proper understanding of the epiphyses is of the utmost possible importance to the student, and greatly simplifies many of the problems in the pathology of bone disease.

Speaking generally, the long bones have at either end an epiphysis from the cartilage of which growth occurs, and hence the shaft of the bone increases in length at both ends. In every case, however, one epiphysis is the more active, and also continues in its activity for a longer time. This *actively growing epiphysis* is always the one from which the nutrient foramen in the diaphysis is directed, and it unites to the shaft at a later date. It follows, therefore, that the increase in length of a long bone is largely dependent on the epiphysis, and hence anything which interferes with the growth from this epiphyseal line at any time prior to the union of the epiphysis with the shaft must result in a cessation of growth in length of that bone. Thus, when dealing with disease in the neighborhood of this actively growing epiphysis very great care should be taken not to excise or destroy its line of union with the shaft. These epiphyses are particularly prone to become the seat of tuberculous disease, which especially tends to attack the soft, highly vascular cancellous tissue.

Again, the actively growing epiphyseal line is the portion of a long bone which is in the vast majority of cases affected by tumor growth in bone, whether it be innocent or malignant, the former (*viz.*, osteoma) usually appearing about puberty, and the latter (*viz.*, sarcoma) usually toward the end of the active period of epiphyseal growth.

Epiphyseal growth, moreover, has to be considered by the surgeon when he is about to amputate in a child. If the amputation is being performed through a bone, the actively growing epiphysis of which is at the upper end, and which will continue to grow for many years (*i. e.*, humerus and tibia), it will be necessary to make allowance for this and to cut the flaps long; as otherwise, owing to continued growth, the sawed end of the bone will ultimately project through the stump, and a condition known as "*conical stump*" will result. This requires removal of a further portion of the bone.

An inflammatory condition termed *acute epiphysitis* also occurs, although it is not so frequent as the acute infective conditions of the diaphysis, owing to the freer blood supply of the epiphysis; in late years it has been shown that acute epiphysitis in children is very frequently the result of a pneumococcal infection, and it may pass on to complete separation of the epiphysis. In this connection it is worthy of note that some of the epiphyseal lines lie entirely within the capsules of their corresponding joints, in other cases entirely without the capsules; and it must follow that in the former case epiphyseal disease, acute or chronic, becomes, *ipso facto*, practically synonymous with disease of that joint. The best examples of intracapsular epiphyses are those of the head of the femur and the head of the humerus, and the vast majority of all cases of tuberculous disease of the hip starts as a tuberculous epiphysitis about the intracapsular epiphyseal line of the femur; again, cases of acute septic arthritis of the shoulder- or hip-joint generally have their origins in these intracapsular epiphyseal lines, and often result in separation of the affected epiphysis. The other class, or extracapsular epiphysitis, when diseased, do not tend to involve the neighboring joint so readily; and it should be the surgeon's duty to keep the disease from involving the joint. For example, the trochanteric epiphysis of the femur is extracapsular as regards the hip-joint, and the epiphyseal line of the head of the tibia is well below the level of the knee-joint, and should a chronic tuberculous abscess form in the latter situation, it should be attacked from the outside before it has time to spread up and involve the cartilage of the head of the tibia. It is, therefore, of great surgical interest to note in every case the relations which the various epiphyseal lines bear to their respective joint capsules.

A knowledge of the exact periods when the epiphyses become joined to the shaft is often of great importance in medicolegal inquiries. It also aids the surgeon in the diagnosis of many of the injuries to which the joints are liable; for it not infrequently happens, on the application of severe force to a joint, that the epiphysis becomes separated from the shaft, and such injuries may be mistaken for fracture or dislocation.

SPECIAL ANATOMY OF THE SKELETON.

**THE VERTEBRAL OR SPINAL COLUMN, OR THE SPINE
(COLUMNA VERTEBRALIS).**

The **vertebral column** is a flexuous and flexible column formed of a series of bones called **vertebræ**.

The **vertebræ** are thirty-three in number, and have received the names **cervical**, **thoracic**, **lumbar**, **sacral**, and **coccygeal**, according to the position which they occupy; seven are found in the cervical region, twelve in the thoracic, five in the lumbar, five in the sacral, and four in the coccygeal.

This number is sometimes increased by an additional vertebra in one region, or the number may be diminished in one region, the deficiency being supplied by an additional vertebra in another. These observations do not apply to the cervical portion of the vertebral column, as the number of bones forming it is rarely increased or diminished.

The **vertebræ** in the upper three regions of the spine remain separate throughout life, and are known as **true** or **movable** **vertebræ**; but those found in the sacral and coccygeal regions are firmly united in the adult, so as to form two bones—five entering into the formation of the upper bone or **sacrum**, and four into the terminal bone of the spine or **coccyx**. The fused **vertebræ** are known as **false** or **immovable** **vertebræ**.

With the exception of the first and second cervical, the true or movable **vertebræ** present certain common characteristics which are best studied by examining one from the middle of the thoracic region.

GENERAL CHARACTERS OF A VERTEBRA.

A **typic vertebra** consists of two essential parts—an anterior solid segment, the **body**, and a posterior segment, the **arch** (*arcus vertebrae*), or the **neural arch**. The arch is formed of **two pedicles** and **two laminæ**, supporting **seven processes**—viz., four **articular**, two **transverse**, and one **spinous**.

The bodies of the **vertebræ** are placed one upon the other, forming a strong pillar for the support of the cranium and trunk; the arches forming a hollow cylinder behind the bodies for the protection of the spinal cord. The different **vertebræ** are connected by means of the articular processes and the intervertebral fibrocartilages; while the transverse and spinous processes serve as levers for the attachment of muscles which move the different parts of the vertebral column. Lastly, between each pair of **vertebræ** apertures (*foramina intervertebralia*) exist through which the spinal nerves pass.

The **Body** (*corpus vertebrae*) is the largest part of a vertebra. Its **upper** and **lower surfaces** are flattened and rough for the attachment of the intervertebral fibrocartilages, and each presents a rim around its circumference. In **front** it is convex from side to side, concave from above downward. **Behind** it is flat from above downward and slightly concave from side to side. Its anterior surface is perforated by a few small apertures, for the passage of nutrient vessels; while on the posterior surface is a single large, irregular aperture, or occasionally more than one, for the exit of veins, the **venæ basis vertebrae**, from the body of the vertebra.

Pedicles (*radix arcus vertebrae*).—The pedicles are two short, thick pieces of bone, which project backward, one on each side, from the upper part of the

body of the vertebra, at the line of junction of its posterior and lateral surfaces. Each pedicle is a root of the vertebral arch. The concavities above and below the pedicles are the **superior and inferior intervertebral notches** (*incisura vertebralis superior et inferior*); they are four in number, two on each side, the inferior ones being generally the deeper. When the vertebræ are articulated the notches of each contiguous pair of bones form the **intervertebral foramina** (*foramina intervertebralia*), which communicate with the vertebral canal and transmit the spinal nerves and bloodvessels.

Laminæ.—The laminæ are two broad plates of bone which complete the neural arch by fusing together in the middle line behind. They enclose a foramen, the **spinal or vertebral foramen** (*foramen vertebrale*), which serves for the protection of the spinal cord. When the vertebræ are joined they form, with their ligaments, the **vertebral canal** (*canalis vertebralis*). The laminæ are connected to the body by means of the pedicles. Their upper and lower borders are rough, for the attachment of the ligamenta subflava.

Processes. Spinous Process (*processus spinosus*).—The spinous process is a rather long, three-sided mass of bone which projects backward from the junction of the two laminæ and may terminate in a tubercle, and serves for the attachment of muscles and ligaments.

Articular Processes.—The articular processes (*zygapophyses*), four in number, two on each side, spring from the junction of the pedicles with the laminæ. Each **superior process** (*processus articularis superior*) projects upward, its **articular surface** (*facies articularis superior*) being directed more or less backward; each **inferior process** (*processus articularis inferior*) projects downward, its **articular surface** (*facies articularis inferior*) looking more or less forward.¹

Transverse Processes (*processus transversi*).—The transverse processes, two in number, project one at each side from the point where the lamina joins the pedicle, between the superior and inferior articular processes. They also serve for the attachment of muscles and ligaments.

The Cervical Vertebrae (Vertebrae Cervicales) (Fig. 15).

The cervical vertebrae are smaller than those in any other region of the spine, and may be readily distinguished by the foramen in the transverse process, which does not exist in the transverse process of either a thoracic or lumbar vertebra.

Body.—The body is small, comparatively dense, and broader from side to side than from before backward. The *anterior* and *posterior surfaces* are flattened and of equal depth; the former is placed on a lower level than the latter, and its inferior border is prolonged downward, so as to overlap the upper and fore part of the vertebra below. Its *upper surface* is concave transversely, and presents a projecting lip on each side; its *lower surface* is convex from side to side, concave from before backward, and presents laterally a shallow concavity which receives the corresponding projecting lip of the adjacent vertebra.

Pedicles.—The pedicles are directed outward and backward, and are attached to the body midway between the upper and lower borders; so that the superior intervertebral notch is as deep as the inferior, but it is, at the same time, narrower.

Laminæ.—The laminæ are narrow, long, thinner above than below, and overlap each other, enclosing the vertebral foramen, which is very large, and of a triangular form.

Processes. Spinous Process.—The spinous process is short, and bifid at the extremity, to afford greater extent of surface for the attachment of muscles, the

¹ It may, perhaps, be as well to remind the reader that the direction of a surface is determined by that of a line drawn at right angles to it.

SPECIAL ANATOMY OF THE SKELETON.

**THE VERTEBRAL OR SPINAL COLUMN, OR THE SPINE
(COLUMNA VERTEBRALIS).**

The **vertebral column** is a flexuous and flexible column formed of a series of bones called **vertebræ**.

The **vertebræ** are thirty-three in number, and have received the names **cervical**, **thoracic**, **lumbar**, **sacral**, and **coccygeal**, according to the position which they occupy; seven are found in the cervical region, twelve in the thoracic, five in the lumbar, five in the sacral, and four in the coccygeal.

This number is sometimes increased by an additional vertebra in one region, or the number may be diminished in one region, the deficiency being supplied by an additional vertebra in another. These observations do not apply to the cervical portion of the vertebral column, as the number of bones forming it is rarely increased or diminished.

The **vertebræ** in the upper three regions of the spine remain separate throughout life, and are known as **true** or **movable** **vertebræ**; but those found in the sacral and coccygeal regions are firmly united in the adult, so as to form two bones—five entering into the formation of the upper bone or **sacrum**, and four into the terminal bone of the spine or **coccyx**. The fused **vertebræ** are known as **false** or **immovable** **vertebræ**.

With the exception of the first and second cervical, the true or movable **vertebræ** present certain common characteristics which are best studied by examining one from the middle of the thoracic region.

GENERAL CHARACTERS OF A VERTEBRA.

A **typic vertebra** consists of two essential parts—an anterior solid segment, the **body**, and a posterior segment, the **arch** (*arcus vertebrae*), or the **neural arch**. The arch is formed of **two pedicles** and **two laminae**, supporting **seven processes**—viz., four **articular**, two **transverse**, and one **spinous**.

The bodies of the **vertebræ** are placed one upon the other, forming a strong pillar for the support of the cranium and trunk; the arches forming a hollow cylinder behind the bodies for the protection of the spinal cord. The different **vertebræ** are connected by means of the articular processes and the intervertebral fibrocartilages; while the transverse and spinous processes serve as levers for the attachment of muscles which move the different parts of the vertebral column. Lastly, between each pair of **vertebræ** apertures (*foramina intervertebralia*) exist through which the spinal nerves pass.

The **Body** (*corpus vertebrae*) is the largest part of a vertebra. Its **upper** and **lower surfaces** are flattened and rough for the attachment of the intervertebral fibrocartilages, and each presents a rim around its circumference. In **front** it is convex from side to side, concave from above downward. **Behind** it is flat from above downward and slightly concave from side to side. Its anterior surface is perforated by a few small apertures, for the passage of nutrient vessels; while on the posterior surface is a single large, irregular aperture, or occasionally more than one, for the exit of veins, the **venae basis vertebrae**, from the body of the vertebra.

Pedicles (*radix arcus vertebrae*).—The pedicles are two short, thick pieces of bone, which project backward, one on each side, from the upper part of the

body of the vertebra, at the line of junction of its posterior and lateral surfaces. Each pedicle is a root of the vertebral arch. The concavities above and below the pedicles are the **superior and inferior intervertebral notches** (*incisura vertebralis superior et inferior*); they are four in number, two on each side, the inferior ones being generally the deeper. When the vertebræ are articulated the notches of each contiguous pair of bones form the **intervertebral foramina** (*foramina intervertebralia*), which communicate with the vertebral canal and transmit the spinal nerves and bloodvessels.

Laminæ.—The laminæ are two broad plates of bone which complete the neural arch by fusing together in the middle line behind. They enclose a foramen, the **spinal or vertebral foramen** (*foramen vertebrale*), which serves for the protection of the spinal cord. When the vertebræ are joined they form, with their ligaments, the **vertebral canal** (*canalis vertebralis*). The laminæ are connected to the body by means of the pedicles. Their upper and lower borders are rough, for the attachment of the ligamenta subflava.

Processes. Spinous Process (*processus spinosus*).—The spinous process is a rather long, three-sided mass of bone which projects backward from the junction of the two laminæ and may terminate in a tubercle, and serves for the attachment of muscles and ligaments.

Articular Processes.—The articular processes (*zygapophyses*), four in number, two on each side, spring from the junction of the pedicles with the laminæ. Each **superior process** (*processus articularis superior*) projects upward, its **articular surface** (*facies articularis superior*) being directed more or less backward; each **inferior process** (*processus articularis inferior*) projects downward, its **articular surface** (*facies articularis inferior*) looking more or less forward.¹

Transverse Processes (*processus transversi*).—The transverse processes, two in number, project one at each side from the point where the lamina joins the pedicle, between the superior and inferior articular processes. They also serve for the attachment of muscles and ligaments.

The Cervical Vertebrae (Vertebrae Cervicales) (Fig. 15).

The cervical vertebrae are smaller than those in any other region of the spine, and may be readily distinguished by the foramen in the transverse process, which does not exist in the transverse process of either a thoracic or lumbar vertebra.

Body.—The body is small, comparatively dense, and broader from side to side than from before backward. The *anterior* and *posterior surfaces* are flattened and of equal depth; the former is placed on a lower level than the latter, and its inferior border is prolonged downward, so as to overlap the upper and fore part of the vertebra below. Its *upper surface* is concave transversely, and presents a projecting lip on each side; its *lower surface* is convex from side to side, concave from before backward, and presents laterally a shallow concavity which receives the corresponding projecting lip of the adjacent vertebra.

Pedicles.—The pedicles are directed outward and backward, and are attached to the body midway between the upper and lower borders; so that the superior intervertebral notch is as deep as the inferior, but it is, at the same time, narrower.

Laminæ.—The laminæ are narrow, long, thinner above than below, and overlap each other, enclosing the vertebral foramen, which is very large, and of a triangular form.

Processes. Spinous Process.—The spinous process is short, and bifid at the extremity, to afford greater extent of surface for the attachment of muscles, the

¹ It may, perhaps, be as well to remind the reader that the direction of a surface is determined by that of a line drawn at right angles to it.

two divisions being often of unequal size. They increase in length from the fourth to the seventh vertebra.

Articular Processes.—The articular processes are flat, oblique, and of an oval form; the superior are directed backward and upward, the inferior forward and downward.

Transverse Processes.—The transverse processes are short, directed downward, outward, and forward, bifid at their extremity, and marked by a groove along the upper surface, which runs downward and outward from the superior intervertebral notch and serves for the transmission of one of the cervical nerves. They are situated in front of the articular processes and on the outer side of the pedicles. The transverse processes are pierced at their bases by a foramen, for the transmission of the vertebral artery, vein, and a plexus of sympathetic nerves. This foramen is known as the **transverse foramen**, the **costotransverse foramen**, and the **vertebrarterial foramen** (*foramen transversarium*). Each process is formed by two roots—the anterior root, sometimes called the **costal process**, arising from the side of the body, and the homologue of the rib in the thoracic region of the column; the posterior root springs from the junction of the pedicle with the lamina, and corresponds to the transverse process in the thoracic region.

FIG. 15.—Cervical vertebra.

It is by the junction of the two that the foramen for the vertebral vessels is formed. The extremity of each of these roots form the anterior and posterior tubercles of the transverse processes.¹

The peculiar vertebræ in the cervical regions are the *first*, or **atlas**; the *second*, or **axis**; and the *seventh*, or **vertebra prominens**. The great modifications in the form of the atlas and axis are designed to admit of the nodding and rotatory movements of the head.

Atlas.—The atlas (Fig. 16) is so named because it supports the globe of the head. The chief peculiarities of this bone are that it has neither body nor spinous process. The body is detached from the rest of the bone, and forms the odontoid process of the second vertebra; while the parts corresponding to the pedicles join in front to form the anterior arch. The atlas is ring-like, and consists of an anterior arch, a posterior arch, and two lateral masses. The **anterior arch** (*arcus anterior*) forms about one-fifth of the ring; its anterior surface is convex, and presents about its centre a **tubercle** (*tuberculum anterius*), for the attachment of the Longus colli muscle; posteriorly it is concave, and marked by a smooth,

¹ The anterior tubercle of the transverse process of the sixth cervical vertebra is of large size, and is sometimes known as "Chassaignac's," or the "carotid tubercle" (*tuberculum caroticum*). It is in close relation with the carotid artery, which lies in front and a little external to it; so that, as was first pointed out by Chassaignac, the vessel can with ease be compressed against it.

oval facet (*fovea dentis*), covered with cartilage, for articulation with the odontoid process of the axis. The upper and lower borders give attachment to the anterior occipitoatlantal and the anterior atlantoaxial ligaments, which connect it with the occipital bone above and the axis below. The **posterior arch** (*arcus posterior*) forms about two-fifths of the circumference of the bone; it terminates behind in a tubercle (*tuberculum posterius*), which is the rudiment of a spinous process, and gives origin to the *Rectus capitis posticus minor*. The diminutive size of this process prevents any interference in the movements between the atlas and the cranium. The posterior part of the arch presents above and behind a rounded edge for the attachment of the posterior occipitoatlantal ligament, while in front, immediately behind each superior articular process, is a groove (*sulcus arteriæ vertebralis*), sometimes converted into a foramen by a delicate bony spiculum, which arches backward from the posterior extremity of the superior articular process. These grooves represent the superior intervertebral notches, and are peculiar in that they are situated behind the articular processes, instead of in front of them, as in the other vertebræ. They serve for the transmission of the vertebral artery, which, ascending through the foramen in the transverse process, winds around the lateral mass in a backward and inward direction. They also transmit the suboccipital (first spinal) nerve. On the under surface of the poste-

FIG. 16.—First cervical vertebra, or atlas.

rior arch, in the same situation, are two other grooves, placed behind the lateral masses, and representing the inferior intervertebral notches of other vertebræ. They are much less marked than the superior. The lower border also gives attachment to the posterior atlanto-axial ligament, which connects it with the axis. The **lateral masses** (*massæ laterales*) are the most bulky and solid parts of the atlas, in order to support the weight of the head; they present two articulating surfaces above and two below. Each represents one-fifth of the ring. Each **superior process** (*fovea articularis superior*) is of large size, oval, concave, and approaches its companion in front but diverges from it behind; it is directed upward, inward, and a little backward, forming a kind of cup for the corresponding condyle of the occipital bone. The two processes are admirably adapted to the nodding movements of the head. Not infrequently they are partially subdivided by a more or less deep indentation, which encroaches upon each lateral margin. Each **inferior articular process** (*facies articularis inferior*) is circular in form, flattened or slightly concave, and directed downward and inward, articulating with the axis. The inferior processes permit the rotatory movements. Just below the inner margin of each superior articular surface is a small tubercle, for the attachment of the transverse ligament, which, stretching across the ring of the atlas, divides it into two unequal parts or arches; the anterior or smaller

segment receiving the odontoid process of the axis, the posterior allowing the transmission of the spinal cord and its membranes. This part of the vertebral canal is of considerable size, to afford space for the spinal cord; and hence lateral displacement of the atlas may occur without compression of this structure. The **transverse processes** are of large size, project directly outward and downward from the lateral masses, and serve for the attachment of special muscles which assist in rotating the head. They are long, not bifid, and perforated at their bases by a canal for the vertebral artery, which is directed from below, upward, and backward.

Axis.—The axis (*epistropheus*) (Fig. 17) is the pivot upon which the first vertebra, carrying the head, rotates. The most distinctive character of this bone is the strong, prominent process, tooth-like in form, which rises perpendicularly from the upper surface of the body. The **body** is deeper in front than behind, and prolonged downward anteriorly so as to overlap the upper and fore part of the next vertebra. It presents in front a median longitudinal ridge, separating two lateral depressions, for the attachment of the Longus colli muscles of either side. The odontoid process presents two articulating surfaces covered with cartilage; one in front, of an oval form, for articulation with the atlas (*facies articularis anterior*); another behind (*facies articularis posterior*), for the transverse

FIG. 17.—Second cervical vertebra, or axis.

ligament—the latter frequently encroaching on the sides of the process. The **apex** is pointed, and gives attachment to the middle odontoid ligament. Below the apex the process is somewhat enlarged, and presents on either side a rough impression for the attachment of the lateral fasciculi of the odontoid or check ligaments, which connect it to the occipital bone; the **base** of the process, where it is attached to the body, is constricted, so as to prevent displacement from the transverse ligament, which binds it in this situation to the anterior arch of the atlas. The **pedicles** are broad and strong, especially their anterior extremities, which coalesce with the sides of the body and the root of the odontoid process. The **laminae** are thick and strong, and the spinal foramen large, but smaller than that of the atlas. The **transverse processes** are very small, not bifid, and each is perforated by the foramen for the vertebral artery, which is directed obliquely upward and outward. The **superior articular surfaces** (*facies articulares superiores*) are circular, slightly convex, directed upward and outward, and are peculiar in being supported on the body, pedicles, and transverse processes. The **inferior articular surfaces** (*facies articulares inferiores*) have the same direction as those of the other cervical vertebrae. The **superior intervertebral notches** are very shallow, and lie behind the articular processes; the inferior in front of them,

as in the other cervical vertebræ. The **spinous process** is of large size, very strong, deeply channelled on its under surface, and presents a bifid, tubercular extremity for the attachment of muscles which serve to rotate the head upon the spine.

Seventh Cervical (Fig. 18).—The most distinctive character of this vertebra is the existence of a very long and prominent spinous process, hence the name, *vertebra prominens*. This process is thick, nearly horizontal in direction, not bifurcated, and gives attachment to the lower end of the ligamentum nuchæ. The **transverse process** is usually of large size, its posterior tubercles are large and prominent, while the anterior are small and faintly marked; its upper surface has usually a shallow groove, and it seldom presents more than a trace of bifurcation at its extremity. The foramen in the transverse process is sometimes as large as in the other cervical vertebræ, but is usually smaller on one or both sides, and is sometimes absent. Usually the vertebral artery and vein pass in front of the transverse process, but occasionally it is traversed on both sides by these vessels, or the left one alone may give passage to them. Occasionally the anterior root of the transverse process exists as a separate bone, and attains a large size. It is then called a **cervical rib**.

FIG. 18.—Seventh cervical vertebra.

The Thoracic Vertebræ (Vertebrae Thoracales).

The **thoracic vertebræ** are intermediate in size between those in the cervical and those in the lumbar region, and increase in size from above downward, the upper vertebræ in this segment of the column being much smaller than those in the lower part. A thoracic vertebra may be at once recognized by the presence on each side of the body of one or more facets or half-facets for the heads of the ribs.

Bodies.—The bodies of the thoracic vertebræ resemble those in the cervical and lumbar regions at the respective ends of this portion of the vertebral column, but in the middle of the thoracic region their form is very characteristic, being heart-shaped, and as broad in the antero-posterior as in the lateral direction. They are thicker behind than in front, flat above and below, convex and prominent in front, deeply concave behind, slightly constricted in front and at the sides, and marked on each side, near the root of the pedicle, by two demi-facets, one above, the other below (*fovea costalis superior et inferior*). These are covered by cartilage in the recent state, and, when articulated with the adjoining vertebræ, form, with the intervening fibrocartilage, oval surfaces for the reception of the heads of the corresponding ribs.

Pedicles.—The pedicles are directed backward, and the inferior intervertebral notches are of large size, and deeper than in any other region of the spine.

Laminæ.—The laminæ are broad, thick, and imbricated—that is to say, overlapping one another like tiles on a roof. The vertebral foramen is small, and of a circular form.

Processes. Spinous Processes.—Each spinous process is long, triangular on transverse section, directed obliquely downward, and terminates in a tubercular extremity. They overlap one another from the fifth to the eighth vertebra, but are less oblique in direction above and below.

Articular Processes.—The articular processes are flat, nearly vertical in direction, and project from the upper and lower part of the pedicles; the superior being directed backward and slightly outward and upward, the inferior forward and a little inward and downward.

FIG. 19.—A thoracic vertebra.

Transverse Processes.—The transverse processes arise from the same parts of the arch as the posterior roots of the transverse processes in the neck, and are situated behind the articular processes and pedicles; they are thick, strong, and of great length, directed obliquely backward and outward, presenting a clubbed extremity, and having on its anterior part near its tip a small concave surface, for articulation with the tubercle of a rib (*fovea costalis transversalis*). Besides the articular facet for the rib, three indistinct tubercles may be seen arising from the transverse processes—one at the upper border, one at the lower border, and one externally. In man they are of comparatively small size, and serve only for the attachment of muscles. But in some animals they attain considerable magnitude, either for the purpose of more closely connecting the segments of this portion of the vertebral column or for muscular and ligamentous attachment.

The peculiar thoracic vertebræ are the *first, ninth, tenth, eleventh, and twelfth* (Fig. 20).

First Thoracic Vertebra.—The first thoracic vertebra presents, on each side of the body, a single entire articular facet for the head of the first rib and a demi-facet for the upper half of the second. The body is like that of a cervical vertebra, being broad transversely, its upper surface is concave, and lipped on each side. The articular surfaces are oblique, and the spinous process thick, long, and almost horizontal.

Ninth Thoracic Vertebra.—The ninth thoracic vertebra has no demi-facet below. In some subjects, however, the ninth has two demi-facets on each side; when this occurs the tenth has only a demi-facet at the upper part.

Tenth Thoracic Vertebra.—The tenth thoracic vertebra has (except in the case just mentioned) an entire articular facet on each side, above, which is partly placed on the outer surface of the pedicle. It has no demi-facet below. Sometimes it has no facet on its transverse process.

FIG. 20.—Peculiar thoracic vertebræ.

Eleventh Thoracic Vertebra.—The body of this vertebra approaches in its form and size that of the lumbar vertebræ. The articular facets for the heads of the ribs, one on each side, are of large size, and placed chiefly on the pedicles, which are thicker and stronger in this and the next vertebra than in any other part of the thoracic region. The **spinous process** is short, and nearly horizontal in direction. The **transverse processes** are very short, tubercular at their extremities, and have no articular facets for the tubercles of the ribs.

Twelfth Thoracic Vertebra.—The twelfth thoracic vertebra has the same general characters as the eleventh, but may be distinguished from it by the inferior articular processes being convex and turned outward, like those of the lumbar vertebræ; and by the fact that this vertebra resembles the lumbar vertebræ in the general form of the body, laminæ, and spinous process; and by the transverse processes being shorter, and marked by three elevations, the superior, inferior, and external tubercles, which correspond to the mammillary, accessory, and transverse processes of the lumbar vertebræ. There is no facet on its transverse process for the twelfth rib.

The Lumbar Vertebræ (*Vertebrae Lumbales*) (Fig. 21).

The lumbar vertebræ are the largest segments of the vertebral column, and can at once be distinguished by the absence of the foramen in the transverse process, the characteristic point of the cervical vertebræ, and by the absence of any articulating facet on the side of the body, the distinguishing mark of the thoracic vertebræ.

FIG. 21.—Lumbar vertebra.

Body.—The body is large, and has a greater diameter from side to side than from before backward, slightly thicker in front than behind, flattened or slightly concave above and below, concave behind, and deeply constricted in front and at the sides, presenting prominent margins, which afford a broad surface for the support of the superincumbent weight.

Pedicles.—The pedicles are very strong, directed backward from the upper part of the bodies; consequently, the inferior intervertebral notches are of considerable depth.

Laminæ.—The laminæ are broad, short, and strong, and the vertebral foramen triangular, larger than in the thoracic, smaller than in the cervical, region.

Processes. Spinous Processes.—The spinous processes are thick and broad, somewhat quadrilateral, horizontal in direction, thicker below than above, and terminating in a rough, uneven border.

Articular Processes.—The superior articular processes are concave, and look backward and inward; the inferior are convex, and look forward and outward; the former are separated by a much wider interval than the latter, embracing the lower articulating processes of the vertebra above.

Transverse Processes.—The transverse processes are long, slender, directed transversely outward in the upper three lumbar vertebræ, slanting a little upward in the lower two. They are situated in front of the articular processes, instead

of behind them, as in the thoracic vertebræ, and are homologous with the ribs. Of the three tubercles noticed in connection with the transverse processes of the twelfth thoracic vertebra, the superior one on each side becomes connected in this region with the back part of the superior articular process, and has received the name of **mammillary process** (*processus mammillaris*); the inferior is represented by a small process pointing downward, situated at the back part of the base of the transverse process, and called the **accessory process** (*processus accessorius*); these are the true transverse processes, which are rudimentary in this region of the spine. The external one, the so-called **transverse process**, is the homologue of the rib, and constitutes the **costal process** (*processus costarius*) (Fig. 22). Although in man the costal processes are comparatively small, in some animals they attain considerable size, and serve to lock the vertebræ more closely together.

FIG. 22.—Lumbar vertebra, viewed obliquely.

Fifth Lumbar Vertebra.—The fifth lumbar vertebra is characterized by having the body much thicker in front than behind, which accords with the prominence of the sacrovertebral articulation; by the smaller size of its spinous process; by the wide interval between the inferior articulating processes; and by the greater size and thickness of its transverse processes, which spring from the body as well as from the pedicles.

Attachment of Muscles.—To the **Atlas** are attached *nine* pairs: the Longus colli, Rectus capitis anticus minor, Rectus lateralis, Obliquus capitis superior and inferior, Splenius colli, Levator anguli scapulae, First Intertransverse, and Rectus capitis posticus minor.

To the **Axis** are attached *eleven* pairs: the Longus colli, Levator anguli scapulae, Splenius colli, Scalenus medius, Transversalis colli, Intertransversales, Obliquus capitis inferior, Rectus capitis posticus major, Semispinalis colli, Multifidus spinae, Interspinales.

To the remaining vertebræ, generally, are attached thirty-five pairs and a single muscle: anteriorly, the Rectus capitis anticus major, Longus colli, Scalenus anticus, medius, and posticus, Psoas magnus and parvus, Quadratus lumborum, Diaphragm, Obliquus abdominis internus, and Transversalis abdominis; posteriorly, the Trapezius, Latissimus dorsi, Levator anguli scapulae, Rhomboideus major and minor, Serratus posticus superior and inferior, Splenius, Erector spinae, Iliocostalis, Longissimus dorsi, Spinalis dorsi, Cervicalis ascendens, Trans-

versalis colli, Trachelomastoid, Complexus, Biventer cervicis, Semispinalis dorsi and colli, Multifidus spinae, Rotatores spinae, Interspinales, Supraspinales, Intertransversales, Levatores costarum.

The Sacral and Coccygeal Vertebrae.

The **sacral** and **coccygeal vertebrae** consist, at an early period of life, of nine separate pieces, which are united in the adult so as to form two bones, five entering into the formation of the sacrum, four into that of the coccyx. Occasionally, the coccyx consists of five bones.¹

Sacrum (*os sacrum*).—The sacrum is a large, triangular bone (Fig. 23), situated at the lower part of the vertebral column, and at the upper and back part of the pelvic cavity, where it is inserted like a wedge between the two innominate bones; its upper part or base articulating with the last lumbar vertebra,

FIG. 23.—Sacrum, anterior surface.

its apex with the coccyx. It is composed of five segments of bone. The sacrum is curved upon itself, and placed very obliquely, its upper extremity projecting forward, and forming, with the last lumbar vertebra, a very prominent angle, called the **promontory** (*promontorium*), or **sacrovertebral angle**; while its central part is directed backward, so as to give increased capacity to the pelvic cavity. It presents for examination an anterior and posterior surface, two lateral surfaces, a base, an apex, and a central canal.

Surfaces. **Anterior or Pelvic Surface** (*facies pelvina*).—The anterior surface is concave from above downward, and slightly so from side to side. In the

¹ Sir George Humphry describes this as the usual composition of the coccyx. On the Skeleton, p. 456.

middle are seen four **transverse ridges** (*lineae transversae*), indicating the original division of the bone into five separate pieces. The portions of bone intervening between the ridges correspond to the bodies of the vertebræ. The body of the first segment is of large size, and in form resembles that of a lumbar vertebra; the succeeding ones diminish in size from above downward, are flattened from before backward, and curved so as to accommodate themselves to the form of the sacrum, being concave in front, convex behind. At each end of the ridges above mentioned are seen the **anterior sacral foramina** (*foramina sacralia anteriora*), analogous to the intervertebral foramina, four in number on each side, somewhat circular in form, diminishing in size from above downward, and directed outward and forward; they transmit the anterior branches of the sacral nerves and the lateral sacral arteries. External to these foramina is the **lateral mass** (*pars lateralis*), consisting at an early period of life of separate segments; these become blended, in the adult, with the bodies, with each other, and with the posterior transverse processes. Each lateral mass is traversed by four broad, shallow grooves, which lodge the anterior divisions of the sacral nerves as they pass outward, the grooves being separated by prominent ridges of bone, which give attachment to the slips of the Piriformis muscle.

If a vertical section is made through the centre of the sacrum (Fig. 24), the bodies are seen to be united at their circumference by bone, a wide interval being left centrally, which, in the recent state, is filled by intervertebral substance. In some bones this union is more complete between the lower segments than between the upper ones.

Posterior or Dorsal Surface (*facies dorsalis*).—The posterior surface (Fig. 25) is convex and much narrower than the anterior. In the middle line are three or four tubercles, which represent the rudimentary spinous processes of the sacral vertebræ. Of these tubercles, the first is usually prominent, and perfectly distinct from the rest; the second and third are either separate or united into a tubercular ridge (*crista sacralis media*), which diminishes in size from above downward; the fourth usually, and the fifth always, remaining undeveloped. The gap which results from failure of the laminæ to meet in the mid-line is called the **hiatus sacralis**. External to the spinous processes on each side are the laminæ, broad and well marked in the first three pieces; sometimes the fourth, and generally the fifth, are only partially developed and fail to meet in the median line. These partially developed laminæ are prolonged downward as rounded processes, the **sacral cornua** (*cornua sacralia*), and are connected to the cornua of the coccyx. Between them the bony wall of the lower end of the sacral canal is imperfect. External to the laminæ is a linear series of indistinct tubercles representing the articular processes (*cristae sacrales articulares*); the upper pair are large, well

FIG. 24.—Vertical section of the sacrum.

developed, and correspond in shape and direction to the superior articulating processes of a lumbar vertebra; the second and third are small; the fourth and fifth (usually blended together) are situated on each side of the sacral canal and assist in forming the sacral cornua. External to the articular processes are the four posterior sacral foramina (*foramina sacralia posteriora*); they are smaller in size and less regular in form than the anterior, and transmit the posterior branches of the sacral nerves. On the outer side of the posterior sacral foramina is a series of tubercles, the rudimentary transverse processes of the sacral vertebræ (*cristae sacrales laterales*). The first pair of transverse tubercles are large, very distinct, and correspond with each superior angle of the bone; they together with the

FIG. 25.—Sacrum, dorsolateral view.

second pair, which are of small size, give attachment to the horizontal part of the sacroiliac ligament; the third gives attachment to the oblique fasciculi of the posterior sacroiliac ligaments; and the fourth and fifth to the great sacro-sciatic ligaments. The interspace between the spinous and transverse processes on the back of the sacrum presents a wide, shallow concavity, called the **sacral groove**; it is continuous above with the vertebral groove, and lodges the origin of the Multifidus spinae.

Lateral Surface.—The lateral surface, broad above, becomes narrowed into a thin edge below. Its upper half presents in front a broad, ear-shaped surface for articulation with the ilium. This is called the **auricular surface** (*facies auricularis*), and in the fresh state is coated with fibrocartilage. It is bounded posteriorly by deep and uneven impressions, for the attachment of the posterior sacroiliac ligaments. The chief prominence is called the tuberosity (*tuberositas sacralis*). The lower half is thin and sharp, and terminates in a projection called the **inferior**

lateral angle; below this angle is a notch, which is converted into a foramen by articulation with the transverse process of the upper piece of the coccyx, and transmits the anterior division of the fifth sacral nerve. This lower, sharp border gives attachment to the greater and lesser sacrosciatic ligaments, and to some fibres of the *Gluteus maximus* posteriorly, and to the *Coccygeus* in front.

Base (*basis oss. sacri*).—The base of the sacrum, which is broad and expanded, is directed upward and forward. In the middle is seen a large oval articular surface, which is connected with the under surface of the body of the last lumbar vertebra by a fibrocartilaginous disk. It is bounded behind by the large, triangular orifice of the sacral canal. The orifice is formed behind by the laminae and spinous process of the first sacral vertebra: the superior articular processes project from it on each side; they are oval, concave, directed backward and inward, like the superior articular processes of a lumbar vertebra; and in front of each articular process is an intervertebral notch, which forms the lower part of the foramen between the last lumbar and first sacral vertebra. Lastly, on each side of the large oval articular plate is a broad and flat triangular surface of bone, which extends outward, supports the *Psoas magnus* muscle and lumbosacral cord, and is continuous on each side with the iliac fossa. This is called the **ala of the sacrum** (*ala sacralis*), and gives attachment to a few of the fibres of the *Iliacus* muscle. The posterior part of the ala represents the transverse process of the first sacral segment.

Apex (*apex oss. sacri*).—The apex, directed downward and slightly forward, presents a small, oval, concave surface for articulation with the coccyx.

The **Sacral Canal** (*canalis sacralis*) runs throughout the greater part of the bone; it is large and triangular in form above, small and flattened, from before backward, below. In this situation its posterior wall is incomplete, from the non-development of the laminae and spinous processes (*hiatus sacralis*). It lodges the sacral nerves, and is perforated by the anterior and posterior sacral foramina, through which these pass out. It constitutes the sacral continuation of the vertebral canal (Fig. 24).

Differences in the Sacrum of the Male and Female.—The sacrum in the female is shorter and wider than in the male; the lower half forms a greater angle with the upper, the upper half of the bone being nearly straight, the lower half presenting the greatest amount of curvature. The bone is also directed more obliquely backward, which increases the size of the pelvic cavity; but the sacrovertebral angle projects less. In the male the curvature is more evenly distributed over the whole length of the bone, and is altogether greater than in the female.

Variations.—This bone, in some cases, consists of six pieces; occasionally the number is reduced to four. Sometimes the bodies of the first and second segments are not joined or the laminae and spinous processes have not coalesced. Occasionally the upper pair of transverse tubercles are not joined to the rest of the bone on one or both sides; and, lastly, the sacral canal may be open for nearly the lower half of the bone, in consequence of the imperfect development of the laminae and spinous processes. The sacrum, also, varies considerably with respect to its degree of curvature.

Articulations.—With four bones: the last lumbar vertebra, coccyx, and the two innominate bones.

Attachment of Muscles.—To eight pairs: in front, the *Pyriformis* and *Coccygeus*, and a portion of the *Iliacus* to the base of the bone; behind, the *Gluteus maximus*, *Latissimus dorsi*, *Multifidus spinæ*, and *Erector spinæ*, and sometimes the *Extensor coccygis*.

Coccyx (*os coccygis*).—The coccyx (Fig. 26) is usually formed of four small segments of bone, the most rudimentary parts of the vertebral column (**vertebrae coccygeae**). In each of the first three segments may be traced a rudimentary body, articular and transverse processes; the last piece (sometimes the third) is a mere nodule of bone, without distinct processes. All the segments are destitute of pedicles, laminae, and spinous processes, and consequently of interverte-

bral foramina and vertebral canal. The first segment is the largest; it resembles the lowermost sacral vertebra, and often exists as a separate piece; the last three, diminishing in size from above downward, are usually blended together so as to form a single bone. The gradual diminution in the size of the pieces gives this bone a triangular form, the base of the triangle joining the apex of the sacrum. It presents for examination an anterior and posterior surface, two borders, a base, and an apex.

FIG. 26.—Coccyx.

Surfaces. Anterior Surface.—The anterior surface is slightly concave and marked with three transverse grooves, indicating the points of junction of the different pieces. It has attached to it the anterior sacrococcygeal ligament and Levator ani muscle, and supports the lower end of the rectum.

Posterior Surface.—The posterior surface is convex, marked by transverse grooves similar to those on the anterior surface; and presents on each side a lineal row of tubercles, the rudimentary articular processes of the coccygeal vertebræ. Of these, the superior pair are large, and are called the **cornua of the coccyx** (*cornua coccygea*); they project upward, and articulate with the cornua of the sacrum, the junction between these two bones completing the fifth posterior sacral foramen for the transmission of the posterior division of the fifth sacral nerve.

Borders.—The lateral borders are thin, and present a series of small eminences, which represent the transverse processes of the coccygeal vertebræ. Of these, the first on each side is the largest, flattened from before backward, and often ascends to join the lower part of the thin lateral edge of the sacrum, thus completing the fifth anterior sacral foramen for the transmission of the anterior division of the fifth sacral nerve; the others diminish in size from above downward, and are often wanting. The borders of the coccyx are narrow, and give attachment on each side to the sacrosciatic ligaments, to the Coccygeus muscles in front of the ligaments, and to the Gluteus maximus behind them.

Base.—The base presents an oval surface for articulation with the sacrum.

Apex.—The apex is rounded, and has attached to it the tendon of the external Sphincter muscle. It is occasionally bifid, and sometimes deflected to one or other side.

Articulation.—With the sacrum.

Attachment of Muscles.—To four pairs and one single muscle: on either side, the Coccygeus; behind, the Gluteus maximus and Extensor coccygis, when present; at the apex, the Sphincter ani; and in front, the Levator ani.

Structure of the Vertebræ.—The body is composed of light, spongy, cancellous tissue, having a thin coating of compact tissue on its external surface perforated by numerous orifices of various sizes for the passage of vessels; its interior is traversed by one or two large canals

(for the reception of veins), which converge toward a single large, irregular aperture or several small apertures at the posterior part of the body of each bone. The arch and processes projecting from it have, on the contrary, an exceedingly thick covering of compact tissue (Fig. 27).

The **sacrum** and **coccyx** consist mainly of spongy bone covered by a thin layer of compact bone.

FIG. 27.—Bony structure of a lumbar vertebra. (Poirier and Charpy.)

Development.—Each vertebra is formed of *four* primary centres of ossification (Fig. 28), one for each lamina and its processes, and two for the body.¹ Ossification commences in the laminae about the sixth week of fetal life, in the situation where the transverse processes afterward project, the ossific granules spreading backward to the spine, forward into the pedicles, and outward into the transverse and articular processes. Ossification in the body commences in the middle of the cartilage about the eighth week by two closely approximated centres, which speedily coalesce to form one central ossific point. According to some authors, ossification commences in the laminae only in the upper vertebrae—*i. e.*, in the cervical and upper thoracic. The first ossific points in the lower vertebrae are those which are to form the body, the osseous centres for the laminae appearing at a subsequent period. At birth these three pieces are entirely separate. During the first year the laminae become united behind, the union taking place first in the lumbar vertebrae and then extending upward through the thoracic and lower cervical vertebrae. About the third year the body is joined to the arch on each side in such a manner that the body is formed from the three original centres of ossification, the amount contributed by the pedicles increasing in extent from below upward. Thus, the bodies of the sacral vertebrae are formed almost entirely from the central nuclei; the bodies of the lumbar are formed laterally and behind by the pedicles; in the thoracic region the pedicles advance as far forward as the articular depressions for the head of the ribs, forming these cavities of reception; and in the neck the lateral portions of the bodies are formed entirely by the advance of the pedicles. The line along which union takes place between the body and the neural arch is named **neurocentral suture**. Before puberty no other changes occur, excepting a gradual increase in the growth of these primary centres; the upper and under surfaces of the bodies and the ends of the transverse and spinous processes being tipped with cartilage, in which ossific granules are not as yet deposited. At sixteen years (Fig. 30) three secondary centres appear, one for the tip of each transverse process, and one for the extremity of the spinous process. In some of the lumbar vertebrae, especially the first, second, and third, a second ossifying centre appears at the base of the spinous process. At twenty-one years (Fig. 29) a thin, circular, epiphyseal plate of bone is formed in the layer of cartilage situated on the upper and under surfaces of the body, the former being the thicker of the two. These represent two additional secondary centres of ossification. All these become joined, and the bone is completely formed between the twenty-fifth and thirtieth year of life.

Exceptions to this mode of development occur in the first, second, and seventh cervical, and in the vertebrae of the lumbar region.

Atlas (Fig. 31).—The number of centres of ossification of the atlas is quite variable. It may be developed from *two, three, four, or five* centres. The most frequent method is from three centres. Two of these are destined for the two lateral or neural masses, the ossification of which commences about the seventh week near the articular processes, and extends backward; these portions of bone are separated from one another behind, at birth, by a narrow interval filled in with cartilage. Between the third and fourth years they unite either directly or through the medium of a separate centre developed in the cartilage in the median line. The anterior

¹ By many observers it is asserted that the bodies of the vertebra are developed from a single centre which speedily becomes bilobed, so as to give the appearance of two nuclei; but that there are two centres, at all events sometimes, is evidenced by the facts that the two halves of the body of the vertebra may remain distinct throughout life, and be separated by a fissure through which a protrusion of the spinal membrane may take place, constituting an *anterior spina bifida*.

arch, at birth, is altogether cartilaginous, and in this a separate nucleus appears about the end of the first year after birth, and, extending laterally, joins the neural processes in front of the pedicles. Sometimes there are two centres developed in the cartilage, one on either side of the median line, which join to form a single mass.

And occasionally there is no separate centre, but the anterior arch is formed by the gradual extension forward and ultimate junction of the two neural processes.

Axis.—The axis (Fig. 32) is developed by seven centres, five primary and two secondary. The body and arch of this bone are formed in the same manner as the corresponding parts in the other vertebrae: one centre (or two, which speedily coalesce) for the lower part of the body, and one for each lamina. The centres for the laminae appear about the seventh or eighth week, that for the body about the fourth month. The odontoid process consists originally of an extension upward of the cartilaginous mass in which the lower part of the body is formed. At about the sixth month of fetal life two centres make their appearance in the base of this process; they are placed laterally, and join before birth to form a conical bilobed mass deeply cleft above; the interval between the cleft and the summit of the process is formed by a wedge-shaped piece of cartilage, the base of the process being separated from the body by a cartilaginous interval, which gradually becomes ossified at its circumference, but remains cartilaginous in its centre until advanced age. Finally, the apex of the odontoid process has a separate (secondary) centre, which appears in the second year and joins about the twelfth year. In addition to these there is a secondary centre for a thin epiphyseal plate on the under surface of the body of the bone.

Seventh Cervical.—The anterior or costal part of the transverse process of the seventh cervical is developed from a separate osseous centre at about the sixth month of fetal life, and joins the body and posterior division of the transverse process between the fifth and sixth years. Sometimes this process continues as a separate piece, and, becoming lengthened outward, constitutes what is known as a cervical rib. This separate ossific centre for the costal process has also been found in the fourth, fifth, and sixth cervical vertebrae.

Lumbar Vertebrae.—The lumbar vertebrae (Fig. 33) have two additional centres (besides those peculiar to the vertebrae generally) for the mammillary tubercles, which project from the back part of the superior articular processes. The transverse process of the first lumbar is sometimes developed as a separate piece, which may remain per-

Exceptional cases.

manently unconnected with the remaining portion of the bone, thus forming a lumbar rib—a peculiarity.

The **sacrum**, formed by the union of five vertebræ, has *thirty-five* centres of ossification.

The **bodies** of the sacral vertebræ have each three ossific centres—one for the central part, and one for the epiphyseal plates on its upper and under surface. Occasionally the primary centres for the bodies of the first and second piece of the sacrum are double. The **arch** of each sacral vertebra is developed from two centres, one for each lamina. These unite with each other behind, and subsequently join the body.

The **lateral masses** have six additional centres, two for each of the first three vertebræ. These centres, representing costal elements, make their appearance above and to the outer side of the anterior sacral foramina (Fig. 34), and are developed into separate segments (Fig. 35); they are subsequently blended with each other, and with the bodies and transverse processes to form the lateral mass.

Lastly, each **lateral surface** of the sacrum is developed from two epiphyseal plates (Fig. 36)—one for the auricular surface, and one for the remaining part of the thin lateral edge of the bone.

FIG. 34.—Development of the sacrum.

FIG. 35

FIG. 36

Period of Development.—At about the eighth or ninth week of fetal life ossification of the central part of the bodies of the first three vertebræ commences, and between the fifth and eighth months in the last two. Between the sixth and eighth months ossification of the laminae takes place; and at about the same period the centres for the lateral masses for the first three sacral vertebræ make their appearance. The period at which the arch becomes completed by the junction of the laminae with the bodies in front and with each other behind varies in different segments. The junction between the laminae and the bodies takes place first in the lower vertebræ as early as the second year, but is not effected in the uppermost until the fifth or sixth year. About the sixteenth year the epiphyses for the upper and under surfaces of the bodies are formed, and between the eighteenth and twentieth years those for each lateral surface of the sacrum make their appearance. The bodies of the sacral vertebræ are, during early life, separated from each other by intervertebral disks. At about the eighteenth year the two lowest segments become joined by ossification extending through the disk. This process gradually extends upward until all the segments become united, and the bone is completely formed from the twenty-fifth to the thirtieth year of life.

FIG. 37.—Base of sacrum at an early stage.

The **coccyx** is developed from *four* centres, one for each piece. Occasionally one of the first three pieces of this bone is developed from two centres, placed side by side. The ossific nuclei make their appearance in the following order: In the first segment, between the first and fourth years; in the second piece, at from five to ten years; in the third, from ten to fifteen years; in the fourth from fourteen to twenty years. As age advances these various segments become united with each other from below upward, the union between the first and second segments being frequently delayed until after the age of twenty-five or thirty. At a late period of life, especially in females, the coccyx often becomes ankylosed to the end of the sacrum.

The Vertebral Column as a Whole.

The vertebral column (*columna vertebralis*), formed by the interarticulation of the vertebræ, is situated in the median line, in the posterior part of the trunk; its average length is about two feet two or three inches (65 to 67.5 cm.), measuring along the curved anterior surface of the column. Of this length, the cervical part measures about five, the thoracic about eleven, the lumbar about seven inches, and the sacrum and coccyx the remainder. The female column is about one inch less than that of the male.

Viewed laterally (Fig. 38), the spinal column presents several curves which correspond to the different regions of the column, and are called cervical, thoracic, lumbar, and pelvic. The **cervical curve** commences at the apex of the odontoid process, and terminates at the middle of the second thoracic vertebra; it is convex in front, and is the least marked of all the curves. The **thoracic curve**, which is concave forward, commences at the middle of the second, and terminates at the middle of the twelfth thoracic vertebra. Its most prominent point behind corresponds to the spine of the seventh thoracic vertebra. The **lumbar curve** commences at the middle of the last thoracic vertebra, and terminates at the sacrovertebral angle. It is convex anteriorly; the convexity of the lower three vertebræ being much greater than that of the upper two. The **pelvic curve** commences at the sacrovertebral articulation and terminates at the point of the coccyx. It is concave anteriorly. The thoracic and pelvic curves are the primary curves, and begin to be formed at an early period of fetal life, and are due to the shape of the bodies of the vertebræ. The cervical and lumbar curves are compensatory or secondary, and are developed after birth in order to maintain the erect position. They are due mainly to the shape of the intervertebral disks. Not uncommonly the thoracic portion of the vertebral column—even in healthy persons—deviates toward the right. This is due to the position of the heart and of the arch of the aorta.

The movable part of the vertebral column presents for examination an anterior, a posterior, and two lateral surfaces; a base, a summit, and the vertebral canal.

FIG. 38.—Lateral view of the vertebral column.

Surfaces.—The **anterior** or **ventral surface** presents the bodies of the vertebræ separated in the recent state by the intervertebral disks. The bodies are broad in the cervical region, narrow in the upper part of the thoracic, and broadest in the lumbar region. The whole of this surface is convex transversely, concave from above downward in the thoracic region, and convex in the same direction in the cervical and lumbar regions.

The **posterior** or **dorsal surface** presents in the median line the spinous processes. These are short, horizontal, with bifid extremities, in the cervical region. In the thoracic region they are directed obliquely above, assume almost a vertical direction in the middle, and are horizontal below, as are also the spines of the lumbar vertebræ. They are separated by considerable intervals in the loins, by narrower intervals in the neck, and are closely approximated in the middle of the thoracic region. On either side of the spinous processes, extending the whole length of the column, is the **vertebral groove** formed by the laminæ in the cervical and lumbar regions, where it is shallow, and by the laminæ and transverse processes in the thoracic region, where it is deep and broad. In the recent state these grooves lodge the deep muscles of the back. External to each vertebral groove are the articular processes, and still more externally are the transverse processes. In the thoracic region the latter processes stand backward, on a plane considerably posterior to that of like processes in the cervical and lumbar regions. In the cervical region the transverse processes are placed in front of the articular processes, and on the outer side of the pedicles, between the intervertebral foramina. In the thoracic region they are posterior to the pedicles, intervertebral foramina, and articular processes. In the lumbar region they are placed in front of the articular processes, but behind the intervertebral foramina.

The **lateral surfaces** are separated from the dorsal surface by the articular processes in the cervical and lumbar regions, and by the transverse processes in the thoracic region. These surfaces present in front the sides of the bodies of the vertebræ, marked in the thoracic region by the facets for articulation with the heads of the ribs. More posteriorly are the intervertebral foramina, formed by the juxtaposition of the intervertebral notches, oval in shape, smallest in the cervical and upper part of the thoracic regions, and gradually increasing in size to the last lumbar vertebra. They are situated between the transverse processes in the neck, and in front of them in the back and loins, and transmit the spinal nerves.

Base.—The base of that portion of the vertebral column formed by the twenty-four movable vertebræ is formed by the under surface of the body of the fifth lumbar vertebra; and the summit by the upper surface of the atlas.

Vertebral Canal.—The vertebral canal follows the different curves of the vertebral column; it is largest in those regions in which the vertebral column enjoys the greatest freedom of movement, as in the neck and loins, where it is wide and triangular; and is narrow and cylindrical in the back, where motion is more limited.

Surface Form.—The only parts of the vertebral column which lie closely under the skin, and so directly influence surface form, are the apices of the spinous processes. These are always distinguishable at the bottom of a median furrow, which, more or less evident, runs down the mesal line of the back from the external occipital protuberance above to the middle of the sacrum below. Occasionally one of these processes deviates a little from the median line—a fact to be remembered in practice, as irregularities of this kind are attendant also on fracture or displacements of the vertebral column. In the cervical region the furrow is between the Trapezius muscles; in the back and loins it is between the Erector spinae muscles. In the neck the furrow is broad, and terminates in a conspicuous projection, which is caused by the spinous process of the seventh cervical vertebra (*vertebra prominens*). Above this the spinous process of the sixth cervical vertebra may sometimes be seen projecting; the other cervical spines are sunken, and are not visible, though the spine of the axis can be felt, and generally also the spines of the third, fourth, and fifth cervical vertebrae. In the thoracic region the furrow is shallow, and during stooping disappears, and then the spinous processes become more or less visible. The markings produced by these spines are small and close together. In the lumbar region the furrow is deep, and the situation of the lumbar spines is frequently indicated by little pits, or depressions,

especially if the muscles in the loins are well developed and the process incurved. They are much larger and farther apart than in the thoracic region. In the sacral region the furrow is shallower, presenting a flattened area which terminates below at the most prominent part of the posterior surface of the sacrum, formed by the spinous processes of the third sacral vertebra. At the bottom of the furrow may be felt the irregular posterior surface of the bone. Below this, in the deep groove leading to the anus, the coccyx may be felt. The only other portions of the vertebral column which can be felt from the surface are the transverse processes of three of the cervical vertebrae, viz., the first, the sixth, and the seventh. The transverse process of the atlas can be felt as a rounded nodule of bone just below and in front of the apex of the mastoid process, along the anterior border of the Sternomastoid. The transverse process of the sixth cervical vertebra is of surgical importance. If deep pressure be made in the neck in the course of the carotid artery, opposite the cricoid cartilage, the prominent anterior tubercle of the transverse process of the sixth cervical vertebra can be felt. This has been named **Chassaignac's tubercle**, and against it the carotid artery may be most conveniently compressed by the finger. The transverse process of the seventh cervical vertebra can also often be felt. Occasionally the anterior root, or costal process, is large and separate, forming a cervical rib.

Applied Anatomy.—It is frequently necessary to locate certain vertebrae. Several of them can be easily found and identified. The seventh cervical spine is conspicuously prominent, and when the skin over it has been marked with a blue pencil the spine of the sixth cervical above and of the first thoracic below may be located. The spine of the third thoracic vertebra is on a level with the root of the spine of the scapula. The spine of the fourth lumbar vertebra is on a level with the highest point of the iliac crest. When one or two vertebrae have been definitely recognized the other ones can be found by counting the spines from a fixed point or from fixed points. Over the fifth lumbar spine there is no prominence, but a depression. The third sacral spine is on a level with the posterior superior spines of the ilium. The level at which the spinal cord terminates should be known to the surgeon if he proposes to tap the spinal theca (*lumbar puncture*) for diagnostic or therapeutic purposes or for spinal anesthesia. In an adult the cord terminates at the lower border of the first lumbar vertebra, and the theca terminates opposite the body of the third sacral vertebra. In a young child the cord terminates opposite the body of the third lumbar vertebra, and the theca ends at about the same level as in an adult. Hence, in either a child or an adult, a puncture below the level of the fourth lumbar vertebra will inflict no injury upon the cord. In children the puncture is made just beneath the spinous process, and in adults about one-half an inch to either side of the spinous process, although the needle should be made to enter the dura in the median line. In either case the needle is directed upward and forward. As previously pointed out, the surgical anatomy of an infant's spine is not identical with the surgical anatomy of an adult's spine. The umbilicus of an infant is opposite the body of the fourth lumbar vertebra; in an adult it is opposite the spinous process of the third lumbar vertebra. In an infant the base of the sternum is on a level with the top of the seventh cervical spine, and in an adult of the second thoracic spine (A. H. Tubby). The vertebral column may be the seat of tuberculosis, which may destroy the bodies of the vertebrae; in such cases a deflection of the column may be directed either forward or backward. This deflection is produced by the great weight of the trunk on the diseased bone. If the deflection is directed forward, it is called *lordosis*; if backward, *kyphosis*. *Scoliosis* (lateral deviation of the vertebral column) is usually due to a faulty attitude of children while standing or while sitting at school desks.

Occasionally the coalescence of the laminae is not completed, and consequently a cleft is left in the arches of the vertebrae, through which a protrusion of the spinal membranes (dura mater and arachnoid), and sometimes of the spinal cord itself, takes place, constituting a malformation known as *spina bifida* or *hydrorhachitis*. This condition is most common in the lumbosacral region; but it may occur in the thoracic or cervical region, or the arches throughout the whole length of the canal may remain unapproximated. In some rare cases, in consequence of the noncoalescence of the two primary centres from which the body is formed, a similar condition may occur in front of the canal, the bodies of the vertebrae being found cleft and the tumor projecting into the thorax, abdomen, or pelvis, between the lateral halves of the bodies affected.

The construction of the spinal column of a number of pieces, securely connected together and enjoying only a slight degree of movement between any two individual pieces, though permitting of a very considerable range of movement, as a whole, allows a sufficient degree of mobility without any material diminution of strength. The main joints of which the spine is composed, together with the very varied movements to which it is subjected, render it liable to *sprains*, which may complicate other injuries or may exist alone; but so closely are the individual vertebrae articulated that these sprains are seldom severe, and an amount of violence sufficiently great to produce tearing of the ligaments would tend to cause a dislocation or fracture. The further safety of the column and its less liability to injury is provided for by its disposition in curves instead of in one straight line. For it is an elastic column, and must first bend before it breaks; under these circumstances, being made up of three curves, it represents three columns, and greater force is required to produce bending of a short column than of a longer one that is equal to it in breadth and material. Again, the safety of the column is provided for by the interposition of the intervertebral disks between the bodies of the vertebrae, which act as admirable

buffers in counteracting the effects of violent jars or shocks. *Fracture dislocation* of the vertebral column may be caused by direct or indirect violence, or by a combination of the two, as when a person falling from a height strikes against some prominence and is doubled over it. The fractures from indirect violence are the more common, and here the bodies of the vertebræ are compressed, while the arches are torn asunder; while in fractures from direct violence the arches are compressed and the bodies of the vertebræ separated from each other. It will therefore be seen that in both classes of injury the spinal cord is the part least likely to be injured, and may escape damage even when there has been considerable lesion of the bony framework. For, as Mr. Jacobson states, "being lodged in the centre of the column, it occupies neutral ground in respect to forces which might cause fracture. For it is a law in mechanics that when a beam, as of timber, is exposed to breakage and the force does not exceed the limits of the strength of the material, one division resists compression, another laceration of the particles, while the third, between the two, is in a negative condition."¹ Applying this principle to the vertebral column, it will be seen that, whether the fracture dislocation be produced by direct violence or by indirect force, one segment, either the anterior or posterior, will be exposed to compression, the other to laceration, and the intermediate part, where the cord is situated, will be in a neutral state. When a fracture dislocation is produced by indirect violence the displacement is almost always the same, the upper segment being driven forward on the lower, so that the cord is compressed between the body of the vertebra below and the arch of the vertebra above.

The parts of the vertebral column most liable to be injured are (1) the thoracolumbar region, for this part is near the middle of the column, and there is therefore a greater amount of leverage, and, moreover, the portion above is comparatively fixed, and the vertebræ which form it, though much smaller, have nevertheless to bear almost as great a weight as those below; (2) the cervicothoracic region, because here the flexible cervical portion of the vertebral column joins the more fixed thoracic region; and (3) the atlantoaxial region, because it enjoys an extensive range of movement, and, being near the skull, is influenced by violence applied to the head. In fracture dislocation, spinous processes and portions of the laminæ may be removed (*laminectomy*) in order to free the spinal cord from pressure, and to permit the surgeon to explore, to arrest hemorrhage, to remove bone fragments, or to apply sutures. Laminectomy is also resorted to in some cases of *paraplegia* due to *Pott's disease* of the spine.

THE SKULL.

The **Skull**, or superior expansion of the vertebral column, has been described as if composed of four vertebræ, the elementary parts of which are specially modified in form and size, and almost immovably connected, for the reception of the brain and special organs of the senses. These vertebræ are the occipital, parietal, frontal, and nasal. Descriptive anatomists, however, divide the skull into two parts, the Cranium and the Face. The Cranium is composed of *eight* bones, viz., the *occipital*, two *parietals*, *frontal*, two *temporals*, *sphenoid*, and *ethmoid*. The Face is composed of *fourteen* bones, viz., the two *nasals*, two *maxillæ*, two *lacrimals*, two *malars*, two *palates*, two *turbinates*, *vomer*, and *mandible*. The *ossiculi auditus*, the *teeth*, and *Wormian bones* are not included in this enumeration.

Skull, 22 bones	{	Cranium, 8 bones .	{	Occipital.
				Two parietals.
	{	Face, 14 bones . .	{	Frontal.
				Two temporals.
				Sphenoid.
				Ethmoid.
				Two nasals.
				Two maxillæ.
				Two lacrimals.
				Two malars.
				Two palates.
				Two turbinates.
				Vomer.
				Mandible.

The Hyoid Bone, situated at the root of the tongue and attached to the base of the skull by ligaments, has also to be considered in this section.

¹ Holmes' System of Surgery, 1883, vol. i, p. 529.

THE CEREBRAL CRANIUM (CRANIUM CEREBRALE) (THE CALVARIA).**The Occipital Bone (Os Occipitale).**

The **occipital bone** is situated at the back part and base of the cranium, is curved on itself, and is trapezoidal in shape. The bone presents for examination two surfaces, four borders, and four angles.

Surfaces.—The **external surface** is convex. Midway between the summit of the bone and the posterior margin of the foramen magnum—a large oval opening for transmission of the spinal cord—is a prominent tubercle, the **external occipital protuberance** (*protuberantia occipitalis externa*), and, descending from it

FIG. 39.—Occipital bone. Outer surface.

as far as the foramen, a vertical ridge, the **external occipital crest** (*crista occipitalis externa*). This protuberance and crest give attachment to the ligamentum nuchæ, and vary in prominence in different skulls. Passing outward from the occipital protuberance is a semicircular ridge on each side, the **superior curved line** (*linea nuchæ superior*). Above this line there is often a second less distinctly marked ridge, called the **highest curved line** (*linea nuchæ suprema*); to it the epicranial aponeurosis is attached. The bone between these two lines is smoother and denser than the rest of the surface. Running parallel with these from the middle of the crest is another semicircular ridge, on each side, the **inferior curved line** (*linea nuchæ inferior*). The surface of the bone above the linea suprema is rough and porous, and in the recent state is covered by the Occipitofrontalis muscle. The superior and inferior curved lines, together with the surfaces of bone between and below them, serve for the attachment of several muscles.

The superior curved line gives attachment internally to the Trapezius, externally to the muscular origin of the Occipitofrontalis, and to the Sternomastoid to the extent shown in Fig. 39; the depressions between the curved lines to the Complexus internally, the Splenius capitis and Obliquus capitis superior externally. The inferior curved line and the depressions below it afford insertion to the Rectus capitis posticus, major and minor.

The **foramen magnum** (*foramen occipitale magnum*) is a large, oval aperture, its long diameter extending from before backward. It transmits the lower portion of the medulla oblongata and its membranes, the spinal part of the spinal accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, and the occipitoaxial ligaments. Its back part is wide for the transmission of the medulla oblongata, and the corresponding margin rough for the attachment of the dura enclosing it; the fore part is narrower, being encroached upon by the condyles; it has projecting toward it, from below, the odontoid process, and its margins are smooth and bevelled internally to support the medulla oblongata. On each side of the foramen magnum are the condyles for articulation with the atlas. Each **condyle** (*condylus occipitalis*) is convex, oval, or reniform in shape, and directed downward and outward. The condyles converge in front, and encroach slightly upon the anterior segment of the foramen. On the inner border of each condyle is a rough tubercle for the attachment of the ligaments (*check*) which connect this bone with the odontoid process of the axis; while external to them is a rough tubercular prominence, the **transverse** or **jugular process** (*processus jugularis*), channelled in front by a deep notch (*incisura jugularis*), which forms part of the **jugular foramen** (*foramen lacerum posterius*). The under surface of this process presents an eminence (*processus intrajugularis*), which represents the paramastoid process of some mammals. The eminence is occasionally large, and extends as low as the transverse process of the atlas. This surface affords attachment to the Rectus capitis lateralis muscle and to the lateral occipitoatlantal ligament; its upper or cerebral surface presents a deep groove, which lodges part of the lateral sinus, while its external surface is marked by a quadrilateral rough facet, covered with cartilage in the fresh state, and articulating with a similar surface on the petrous portion of the temporal bone. On the outer side of each condyle, near its fore part, is a foramen, the **anterior condylar foramen** (*canalis hypoglossi*); it is directed downward, outward, and forward, and transmits the hypoglossal nerve, and occasionally a meningeal branch of the ascending pharyngeal artery. This foramen is sometimes double. Behind each condyle is a fossa¹ (*fossa condyloideus*), sometimes perforated at the bottom by a foramen, the **posterior condylar foramen** (*canalis condyloideus*), for the transmission of a vein to the lateral sinus. The **basilar process** (*pars basilaris*) is a strong quadrilateral plate of bone, which is wider behind than in front, and is situated in front of the foramen magnum. Its under surface is rough, presents in the median line a tubercular ridge, the **pharyngeal spine** (*tuberculum pharyngeum*), for the attachment of the tendinous raphé and Superior constrictor of the pharynx, and on each side of it rough depressions for the attachment of the Rectus capitis anticus, major and minor.

The **internal surface** (Fig. 40) is deeply concave. The posterior part is divided by a **crucial ridge** into four fossæ. The two superior fossæ receive the occipital lobes of the cerebrum, and present slight eminences and depressions corresponding to their convolutions. The two inferior, which receive the hemispheres of the cerebellum, are larger than the former, and comparatively smooth; both are marked by slight grooves for the lodgement of arteries. At the point of meeting of the four

¹ This fossa presents many variations in size. It is usually shallow, and the foramen small; occasionally wanting on one or both sides. Sometimes both fossa and foramen are large, but confined to one side only; more rarely, the fossa and foramen are very large on both sides.

THE CEREBRAL CRANIUM (CRANIUM CEREBRALE) (THE CALVARIA).

The Occipital Bone (Os Occipitale).

The **occipital bone** is situated at the back part and base of the cranium, is curved on itself, and is trapezoidal in shape. The bone presents for examination two surfaces, four borders, and four angles.

Surfaces.—The **external surface** is convex. Midway between the summit of the bone and the posterior margin of the foramen magnum—a large oval opening for transmission of the spinal cord—is a prominent tubercle, the **external occipital protuberance** (*protuberantia occipitalis externa*), and, descending from it

FIG. 39.—Occipital bone. Outer surface.

as far as the foramen, a vertical ridge, the **external occipital crest** (*crista occipitalis externa*). This protuberance and crest give attachment to the ligamentum nuchæ, and vary in prominence in different skulls. Passing outward from the occipital protuberance is a semicircular ridge on each side, the **superior curved line** (*linea nuchæ superior*). Above this line there is often a second less distinctly marked ridge, called the **highest curved line** (*linea nuchæ suprema*); to it the epicranial aponeurosis is attached. The bone between these two lines is smoother and denser than the rest of the surface. Running parallel with these from the middle of the crest is another semicircular ridge, on each side, the **inferior curved line** (*linea nuchæ inferior*). The surface of the bone above the linea suprema is rough and porous, and in the recent state is covered by the Occipitofrontalis muscle. The superior and inferior curved lines, together with the surfaces of bone between and below them, serve for the attachment of several muscles.

The superior curved line gives attachment internally to the Trapezius, externally to the muscular origin of the Occipitofrontalis, and to the Sternomastoid to the extent shown in Fig. 39; the depressions between the curved lines to the Complexus internally, the Splenius capitis and Obliquus capitis superior externally. The inferior curved line and the depressions below it afford insertion to the Rectus capitis posticus, major and minor.

The **foramen magnum** (*foramen occipitale magnum*) is a large, oval aperture, its long diameter extending from before backward. It transmits the lower portion of the medulla oblongata and its membranes, the spinal part of the spinal accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, and the occipitoaxial ligaments. Its back part is wide for the transmission of the medulla oblongata, and the corresponding margin rough for the attachment of the dura enclosing it; the fore part is narrower, being encroached upon by the condyles; it has projecting toward it, from below, the odontoid process, and its margins are smooth and bevelled internally to support the medulla oblongata. On each side of the foramen magnum are the condyles for articulation with the atlas. Each **condyle** (*condylus occipitalis*) is convex, oval, or reniform in shape, and directed downward and outward. The condyles converge in front, and encroach slightly upon the anterior segment of the foramen. On the inner border of each condyle is a rough tubercle for the attachment of the ligaments (*check*) which connect this bone with the odontoid process of the axis; while external to them is a rough tubercular prominence, the **transverse** or **jugular process** (*processus jugularis*), channelled in front by a deep notch (*incisura jugularis*), which forms part of the **jugular foramen** (*foramen lacerum posterius*). The under surface of this process presents an eminence (*processus intrajugularis*), which represents the paramastoid process of some mammals. The eminence is occasionally large, and extends as low as the transverse process of the atlas. This surface affords attachment to the Rectus capitis lateralis muscle and to the lateral occipitoatlantal ligament; its upper or cerebral surface presents a deep groove, which lodges part of the lateral sinus, while its external surface is marked by a quadrilateral rough facet, covered with cartilage in the fresh state, and articulating with a similar surface on the petrous portion of the temporal bone. On the outer side of each condyle, near its fore part, is a foramen, the **anterior condylar foramen** (*canalis hypoglossi*); it is directed downward, outward, and forward, and transmits the hypoglossal nerve, and occasionally a meningeal branch of the ascending pharyngeal artery. This foramen is sometimes double. Behind each condyle is a fossa¹ (*fossa condyloideus*), sometimes perforated at the bottom by a foramen, the **posterior condylar foramen** (*canalis condyloideus*), for the transmission of a vein to the lateral sinus. The **basilar process** (*pars basilaris*) is a strong quadrilateral plate of bone, which is wider behind than in front, and is situated in front of the foramen magnum. Its under surface is rough, presents in the median line a tubercular ridge, the **pharyngeal spine** (*tuberculum pharyngeum*), for the attachment of the tendinous raphé and Superior constrictor of the pharynx, and on each side of it rough depressions for the attachment of the Rectus capitis anticus, major and minor.

The **internal surface** (Fig. 40) is deeply concave. The posterior part is divided by a **crucial ridge** into four fossæ. The two superior fossæ receive the occipital lobes of the cerebrum, and present slight eminences and depressions corresponding to their convolutions. The two inferior, which receive the hemispheres of the cerebellum, are larger than the former, and comparatively smooth; both are marked by slight grooves for the lodgement of arteries. At the point of meeting of the four

¹ This fossa presents many variations in size. It is usually shallow, and the foramen small; occasionally wanting on one or both sides. Sometimes both fossa and foramen are large, but confined to one side only; more rarely, the fossa and foramen are very large on both sides.

THE CEREBRAL CRANIUM (CRANIUM CEREBRALE) (THE CALVARIA).

The Occipital Bone (Os Occipitale).

The **occipital bone** is situated at the back part and base of the cranium, is curved on itself, and is trapezoidal in shape. The bone presents for examination two surfaces, four borders, and four angles.

Surfaces.—The **external surface** is convex. Midway between the summit of the bone and the posterior margin of the foramen magnum—a large oval opening for transmission of the spinal cord—is a prominent tubercle, the **external occipital protuberance** (*protuberantia occipitalis externa*), and, descending from it

FIG. 39.—Occipital bone. Outer surface.

as far as the foramen, a vertical ridge, the **external occipital crest** (*crista occipitalis externa*). This protuberance and crest give attachment to the ligamentum nuchæ, and vary in prominence in different skulls. Passing outward from the occipital protuberance is a semicircular ridge on each side, the **superior curved line** (*linea nuchæ superior*). Above this line there is often a second less distinctly marked ridge, called the **highest curved line** (*linea nuchæ suprema*); to it the epicranial aponeurosis is attached. The bone between these two lines is smoother and denser than the rest of the surface. Running parallel with these from the middle of the crest is another semicircular ridge, on each side, the **inferior curved line** (*linea nuchæ inferior*). The surface of the bone above the linea suprema is rough and porous, and in the recent state is covered by the Occipitofrontalis muscle. The superior and inferior curved lines, together with the surfaces of bone between and below them, serve for the attachment of several muscles.

The superior curved line gives attachment internally to the Trapezius, externally to the muscular origin of the Occipitofrontalis, and to the Sternomastoid to the extent shown in Fig. 39; the depressions between the curved lines to the Complexus internally, the Splenius capitis and Obliquus capitis superior externally. The inferior curved line and the depressions below it afford insertion to the Rectus capitis posticus, major and minor.

The **foramen magnum** (*foramen occipitale magnum*) is a large, oval aperture, its long diameter extending from before backward. It transmits the lower portion of the medulla oblongata and its membranes, the spinal part of the spinal accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, and the occipitoaxial ligaments. Its back part is wide for the transmission of the medulla oblongata, and the corresponding margin rough for the attachment of the dura enclosing it; the fore part is narrower, being encroached upon by the condyles; it has projecting toward it, from below, the odontoid process, and its margins are smooth and bevelled internally to support the medulla oblongata. On each side of the foramen magnum are the condyles for articulation with the atlas. Each **condyle** (*condylus occipitalis*) is convex, oval, or reniform in shape, and directed downward and outward. The condyles converge in front, and encroach slightly upon the anterior segment of the foramen. On the inner border of each condyle is a rough tubercle for the attachment of the ligaments (*check*) which connect this bone with the odontoid process of the axis; while external to them is a rough tubercular prominence, the **transverse** or **jugular process** (*processus jugularis*), channelled in front by a deep notch (*incisura jugularis*), which forms part of the **jugular foramen** (*foramen lacerum posterius*). The under surface of this process presents an eminence (*processus intrajugularis*), which represents the paramastoid process of some mammals. The eminence is occasionally large, and extends as low as the transverse process of the atlas. This surface affords attachment to the Rectus capitis lateralis muscle and to the lateral occipitoatlantal ligament; its upper or cerebral surface presents a deep groove, which lodges part of the lateral sinus, while its external surface is marked by a quadrilateral rough facet, covered with cartilage in the fresh state, and articulating with a similar surface on the petrous portion of the temporal bone. On the outer side of each condyle, near its fore part, is a foramen, the **anterior condylar foramen** (*canalis hypoglossi*); it is directed downward, outward, and forward, and transmits the hypoglossal nerve, and occasionally a meningeal branch of the ascending pharyngeal artery. This foramen is sometimes double. Behind each condyle is a fossa¹ (*fossa condyloidea*), sometimes perforated at the bottom by a foramen, the **posterior condylar foramen** (*canalis condyloideus*), for the transmission of a vein to the lateral sinus. The **basilar process** (*pars basilaris*) is a strong quadrilateral plate of bone, which is wider behind than in front, and is situated in front of the foramen magnum. Its under surface is rough, presents in the median line a tubercular ridge, the **pharyngeal spine** (*tuberculum pharyngeum*), for the attachment of the tendinous raphé and Superior constrictor of the pharynx, and on each side of it rough depressions for the attachment of the Rectus capitis anticus, major and minor.

The **internal surface** (Fig. 40) is deeply concave. The posterior part is divided by a **crucial ridge** into four fossæ. The two superior fossæ receive the occipital lobes of the cerebrum, and present slight eminences and depressions corresponding to their convolutions. The two inferior, which receive the hemispheres of the cerebellum, are larger than the former, and comparatively smooth; both are marked by slight grooves for the lodgement of arteries. At the point of meeting of the four

¹ This fossa presents many variations in size. It is usually shallow, and the foramen small; occasionally wanting on one or both sides. Sometimes both fossa and foramen are large, but confined to one side only; more rarely, the fossa and foramen are very large on both sides.

divisions of the crucial ridge is an eminence, the **internal occipital protuberance** (*protuberantia occipitalis interna*). It nearly corresponds to that on the outer surface, though it is often on a slightly higher level, and is perforated by one or more large vascular foramina. From this eminence the superior division of the crucial ridge runs upward to the superior angle of the bone; it presents a deep groove, the **sagittal sulcus** (*sulcus sagittalis*), for the superior sagittal sinus. The margins of the groove give attachment to the falx cerebri. The inferior division, the **internal occipital crest** (*crista occipitalis interna*), runs to the posterior margin of the foramen magnum, on the edge of which it becomes gradually lost; this

FIG. 40.—Occipital bone. Inner surface.

ridge, which is bifurcated below, serves for the attachment of the falx cerebelli. It is usually marked by a single groove, which commences at the back part of the foramen magnum and lodges the occipital sinus. Occasionally the groove is double where two sinuses exist. A **transverse groove** (*sulcus transversus*) passes outward on each side to the lateral angle. The grooves are deep channels for the lodgement of the lateral sinuses, their prominent margins affording attachment to the tentorium.¹ At the point of meeting of these grooves is a depression, the **torcular**² (*confluens sinuum*), placed a little to one or the other side of the internal

¹ Usually one of the transverse grooves is deeper and broader than the other; occasionally, both grooves are of equal depth and breadth, or both equally indistinct. The broader of the two transverse grooves is nearly always continuous with the vertical groove for the superior sagittal sinus.

² The columns of blood coming in different directions were supposed to be pressed together at this point (torcular, a wine press).

occipital protuberance. More anteriorly is the foramen magnum, and on each side of it, but nearer its anterior than its posterior part, the internal openings of the anterior condylar foramen. On the superior aspect of the lateral portion of the bone the **jugular tubercle** (*tuberculum jugulare*) is seen. This corresponds to the portion of bone which roofs in the anterior condylar foramen. The internal openings of the posterior condylar foramina are a little external and posterior to the openings of the anterior condylar foramina, protected by a small arch of bone. At this part of the internal surface there is a very deep groove in which the posterior condylar foramen, when it exists, has its termination. This groove is continuous, in the complete skull, with the transverse groove on the posterior part of the bone, and lodges the end of the lateral sinus. In front of the foramen magnum is the basilar process, presenting a shallow depression, the **basilar groove** (*clivus*), which slopes from behind, upward and forward, and supports the medulla oblongata and part of the pons (Varolii), and on each side of the basilar process is a narrow channel, which, when united with a similar channel on the petrous portion of the temporal bone, forms a groove (*sulcus petrosus inferior*), which lodges the inferior petrosal sinus.

Borders.—The **superior border** (*margo lambdoideus*) extends on each side from the superior to the lateral angle, is deeply serrated for articulation with the parietal bone, and forms, by this union, the **lambdoid suture**.

The **inferior border** extends from the lateral to the inferior angle; its upper half (*margo mastoideus*) is rough, and articulates with the mastoid portion of the temporal, forming the **masto-occipital suture**; the inferior half articulates with the petrous portion of the temporal, forming the **petro-occipital suture**; these two portions are separated from each other by the jugular process. In front of this process is a deep notch, which with a similar one on the petrous portion of the temporal forms the jugular foramen (*foramen lacerum posterius*). This notch is occasionally subdivided into two parts by a small process of bone (*processus intrajugularis*), and it generally presents an aperture at its upper part, the internal opening of the posterior condyloid foramen.

Angles.—The **superior angle** is received into the interval between the posterior superior angles of the two parietal bones; it corresponds with that part of the skull in the fetus which is called the posterior fontanelle.

The **inferior angle** is represented by the square-shaped surface of the basilar process. At an early period of life a layer of cartilage separates this part of the bone from the sphenoid, but in the adult the union between them is osseous.

The **lateral angles** correspond to the outer ends of the transverse grooves, and are received into the interval between the posterior inferior angles of the parietal and the mastoid portion of the temporal.

Structure.—The occipital bone consists of two compact laminae, called the **outer** and **inner tables**, having between them the diploic tissue; this bone is especially thick at the ridges, protuberances, condyles, and anterior part of the basilar process; while at the bottom of the fossae, especially the inferior, it is thin, semitransparent, and destitute of diploë.

Development (Fig. 41).—At birth the bone consists of four distinct parts—a **tabular** or **squamous portion**, which lies behind the foramen magnum; two **condylic** parts, which form the sides of the foramen; and a **basilar part**, which lies in front of the foramen. The tabular portion is usually developed from *four* centres, though the number may vary from one to eight; two centres appear near the median line of the bone

FIG. 41.—Development of occipital bone. From seven centres.

during the second month, and two more a little lateral to the preceding during the third month. These parts tend to unite, but complete union does not occur until about the fourth month after birth. That part of the tabular portion above the highest curved line is developed by the *intramembranous method*, and may exist in the adult as a separate element, the **interparietal bone**, or *os inca*, because of its frequent occurrence in Peruvian skulls. The remainder of the tabular portion and the basilar and two condyloid parts are developed from cartilage. Usually two centres appear in the basilar portion during the sixth fetal week, and by rapid coalescence give the appearance of a single centre. Each condylic portion develops from a single centre that appears at about the end of the eighth fetal week. At about the fourth year the tabular and the two condyloid pieces unite, and about the sixth year the bone consists of a single piece. Between the eighteenth and twenty-fifth years the occipital and sphenoid become united, forming a single bone.

Articulations.—With *six* bones—two parietal, two temporal, sphenoid, and atlas.

Attachment of Muscles.—To *twelve* pairs—to the superior curved line are attached the Occipitofrontalis, Trapezius, and Sternomastoid. To the space between the curved lines, the Complexus,¹ Splenius capitis, and Obliquus capitis superior; to the inferior curved line, and the space between it and the foramen magnum, the Rectus capitis posticus, major and minor; to the transverse process, the Rectus capitis lateralis; and to the basilar process, the Rectus capitis anticus, major and minor, and Superior constrictor of the pharynx.

The Parietal Bone (*Os Parietale*).

The **parietal bones** are paired bones, and form, by their union, the sides and roof of the cranium proper. Each bone is of an irregular quadrilateral form, and presents for examination two surfaces, four borders, and four angles.

Surfaces.—The **external surface** (*facies parietalis*) (Fig. 42) is convex, smooth, and marked about its centre by an eminence called the **parietal eminence** (*tuber parietale*), which indicates the point where ossification commenced. Crossing the middle of the bone in an antero-posterior direction are two well-marked curved ridges, the **upper and lower temporal ridges** (*linea temporalis superior et inferior*); the former gives attachment to the temporal fascia, while the latter indicates the upper limit of the origin of the Temporal muscle. These lines form the **temporal crest**. Above these ridges the surface of the bone is covered by the aponeurosis of the Occipitofrontalis; below them the bone forms part of the temporal fossa, and affords attachment to the temporal muscle. At the back part of the superior border, close to the sagittal suture, which separates the two parietal bones, is a small foramen (*foramen parietale*), which transmits the emissary vein of Santorini from the scalp to the superior sagittal sinus. It sometimes also transmits a small branch of the occipital artery. Its existence is not constant, and its size varies considerably.

The **internal or cerebral surface** (*facies cerebralis*) (Fig. 43) is concave, presents depressions for the lodgement of the convolutions of the cerebrum, and numerous furrows for the branches of the middle meningeal artery; the latter runs upward and backward from the anterior inferior angle and from the central and posterior part of the lower border of the bone. Sometimes a distinct canal exists for the artery, but it never remains a canal for a long distance. Along the upper margin of the bone is part of a shallow groove, which, when joined to the opposite parietal, forms a channel for the **superior sagittal sinus**. The elevated edges of the groove afford attachment to the falx cerebri. Near the groove are seen several depressions, **Pacchionian depressions** (*foveolae granulares* [*Pacchioni*]). They are most frequently found in the skulls of old persons, and lodge the arachnoid villi (*Pacchionian bodies*). The internal opening of the parietal foramen is also seen when that aperture exists. On the inner surface of the posterior inferior portion of the bone is a portion of the groove for the lodgement of the lateral sinus.

¹ To these the Biventer cervicis should be added, if it is regarded as a separate muscle.

FIG. 42.—Left parietal bone. External surface.

FIG. 43.—Left parietal bone. Internal surface.

Borders.—The **superior border** (*margo sagittalis*), the longest and thickest, is dentated to articulate with its fellow of the opposite side, forming the **sagittal suture**.

The **inferior border** (*margo squamosus*) is divided into three parts; of these, the anterior is thin and pointed, bevelled at the expense of the outer surface, and overlapped by the tip of the greater wing of the sphenoid; the middle portion is arched, bevelled at the expense of the outer surface, and overlapped by the squamous portion of the temporal; the posterior portion is thick and serrated for articulation with the mastoid portion of the temporal.

The **anterior border** (*margo frontalis*), deeply serrated, is bevelled at the expense of the outer surface above and of the inner below; it articulates with the frontal bone, forming the **coronal suture**.

The **posterior border** (*margo occipitalis*), deeply denticulated, articulates with the occipital, forming the **lambdoid suture**.

Angles.—The **anterior superior angle** (*angulus frontalis*), thin and pointed, corresponds with that portion of the skull which in the fetus is membranous, and is called the **anterior fontanelle** (*bregma*).

The **anterior inferior angle** (*angulus sphenoidalis*) is thin and lengthened, being received in the interval between the greater wing of the sphenoid and the frontal. Its inner surface is marked by a deep groove, sometimes a canal, for the anterior branch of the middle meningeal artery. At the anterior inferior angle the parietal and frontal bones and the greater wing of the sphenoid bone meet. This spot is called the **pterion**.

The **posterior superior angle** (*angulus occipitalis*) corresponds with the junction of the sagittal and lambdoid sutures. In the fetus this part of the skull is membranous, and is called the **posterior fontanelle** (*lambda*).

The **posterior inferior angle** (*angulus mastoideus*) articulates with the mastoid portion of the temporal bone, and generally presents on its inner surface a broad, shallow groove for the lodgement of part of the lateral sinus.

Development.—The parietal bone is formed in membrane, being developed from one centre, which corresponds with the parietal eminence, and makes its first appearance about the seventh or eighth week of fetal life. Ossification gradually extends from the centre to the circumference of the bone; the angles are consequently the parts last formed, and it is in their situation that the fontanelles exist previous to the completion of the growth of the bone. Occasionally the parietal bone is divided into two parts, upper and lower, by an antero-posterior suture.

Articulations.—With five bones—the opposite parietal, the occipital, frontal, temporal, and sphenoid.

Attachment of Muscles.—One only, the Temporal.

The Frontal Bone (*Os Frontale*).

The **frontal bone** consists of two portions—a **vertical** or **frontal** portion, situated at the anterior part of the cranium proper, forming the forehead; and a **horizontal** or **orbital** portion, which enters into the formation of the roof of the orbits and nasal fossæ.

Vertical Portion. Surfaces.—**External Surface** (*facies frontalis*) (Fig. 44).—In the median line, traversing the bone from the upper to the lower part, is occasionally seen a slightly elevated ridge, and in young subjects a suture (*frontal* or *metopic suture*) which represents the line of union of the two lateral halves of which the bone consists at an early period of life; in the adult this suture is usually obliterated and the bone forms one piece. On either side of this ridge, a little below the centre of the bone, is a rounded prominence, the **frontal eminence** (*tuber frontale*). These eminences vary in size in different individuals, and are occasionally unsymmetrical

in the same subject. The whole surface of the bone above this part is smooth, and covered by the aponeurosis of the Occipitofrontalis muscle. Below the frontal eminence and separated from it by a slight groove is the **superciliary ridge** (*arcus superciliaris*), broad internally, where it is continuous with the nasal eminence, but less distinct as it arches outward. These ridges are caused by the projection outward of the frontal air sinuses,¹ and give attachment to the *Orbicularis palpebrarum* and *Corrugator supercilii*. Between the two superciliary ridges is a smooth, flat surface, the **glabella**. Beneath the superciliary ridge is the **supraorbital arch** (*margo supraorbitalis*), a curved and prominent margin, which forms the upper boundary of the orbit and separates the vertical from the horizontal portion of the bone. The outer part of the arch is sharp and prominent, affording to the eye, in that situation, considerable protection from injury;

FIG. 44.—Frontal bone. Outer surface.

the inner part is less prominent. At the junction of the internal and middle third of this arch is a notch, sometimes converted into a foramen, and called the **supraorbital notch** (*incisura supraorbitalis*). It transmits the supraorbital artery, vein, and nerve. A small aperture is seen in the upper part of the notch, which transmits a vein from the diploë to join the supraorbital vein. To the median side of the supraorbital notch there is often a notch (*incisura frontalis*) for the passage of the frontal artery and nerve. The supraorbital arch terminates externally in the **external angular process** and internally in the **internal angular**

¹ Some confusion is occasioned to students commencing the study of anatomy by the name "sinuses" having been given to two perfectly different kinds of spaces connected with the skull. It may be as well, therefore, to state here, at the outset, that the "sinuses" in the interior of the cranium which produce the grooves on the inner surface of the bones are venous channels along which the blood runs in its passage back from the brain, while the "sinuses" external to the cranial cavity (the frontal sphenoidal, ethmoidal, and maxillary) are hollow spaces in the bones themselves which communicate with the nostrils, and contain air.

process. The external angular process is strong, prominent, and articulates with the malar bone; running upward and backward from it are two well-marked lines, which, starting together from the external angular process as the **temporal crest**, soon diverge from each other and run in a curved direction across the bone. These are the **upper and lower temporal ridges**; the upper gives attachment to the temporal fascia, the lower to the Temporal muscle. Beneath them is a slight concavity that forms the anterior part of the temporal fossa and gives origin to the Temporal muscle. The internal angular process is less marked than the external, and articulates with the lacrimal bones.

FIG. 45.—Frontal bone. Inner surface.

Internal Surface (*cerebral surface, facies cerebialis*) (Fig. 45).—Along the median line is a vertical groove, the **sulcus sagittalis**, the edges of which unite below to form a ridge, the **frontal crest** (*crista frontalis*); the groove lodges the superior sagittal sinus, while its margins afford attachment to the falx cerebri. The crest terminates below at a small notch which is converted into a foramen by articulation with the ethmoid. It is called the **foramen cecum**, and varies in size in different subjects; it is sometimes partially or completely impervious, lodges a process of the falx, and when open transmits a vein from the mucous membrane of the nose to the superior sagittal sinus. On either side of the groove the bone is deeply concave, presenting depressions for the convolutions of the brain, and numerous small furrows for the ramifications of the anterior branches of the middle meningeal arteries. Several small, irregular fossæ are seen also on either side of the groove, for the reception of the arachnoid villi.

The **border** of the vertical portion is thick, deeply serrated, bevelled at the

expense of the internal table above, where it rests upon the parietal bones, and at the expense of the external table at each side, where it receives the lateral pressure of those bones; this border is continued below into a triangular rough surface which articulates with the greater wing of the sphenoid.

Horizontal or Orbital Portion.—This portion of the bone consists of two thin plates, the **orbital plates**, which form the vault of the orbit, separated from one another by a median gap, the **ethmoidal notch**.

Surfaces. Orbital Surface.—The surface of each orbital plate (*facies orbitalis*) consists of a smooth, concave, triangular lamina of bone, marked at its front and external part (immediately beneath the external angular process) by a shallow depression, the **lacrimal fossa** (*fossa glandulae lacrimalis*), occupied by the lacrimal gland; and at its anterior and internal part by a depression (sometimes a small tubercle), the **trochlear fossa** (*fovea trochlearis*), for the attachment of the cartilaginous pulley of the Superior oblique muscle of the eye. These plates are united in front by a roughened uneven surface called the nasal process, which articulates in front with the nasal bones, laterally with the nasal process of each maxilla. From the middle of the nasal process a thin lamina of bone (the *nasal spine*) projects downward and forward; on either side of this is a shallow groove, which enters into the formation of the nasal fossa. The nasal spine forms part of the septum of the nose, articulating in front with the nasal bones and behind with the perpendicular plate of the ethmoid. The **ethmoidal notch** (*incisura ethmoidalis*) separates the two orbital plates; it is quadrilateral, and occupied, when the bones are united, by the cribriform plate of the ethmoid. The margins of this notch present several half cells, which, when united with corresponding half cells on the upper surface of the ethmoid, complete the **ethmoidal cells**; two grooves are also seen crossing these edges obliquely; they are converted into canals by articulation with the ethmoid, and are called the **anterior** and **posterior ethmoidal canals** (*foramen ethmoidale anterius* and *foramen ethmoidale posterius*); they open on the inner wall of the orbit. The anterior one transmits the nasal nerve and anterior ethmoidal vessels, the posterior one the posterior ethmoidal vessels. In front of the ethmoidal notch, on each side of the nasal process, is the opening of the **frontal air sinus** (*sinus frontalis*). These are two irregular cavities, which extend upward and outward, a variable distance, between the two tables of the skull, and are separated from each other by a thin bony septum (*septum sinuum frontalem*), which is often displaced to one side. Within the sinuses imperfect trabeculae of bone often exist. The sinuses are beneath and give rise to the prominences above the supraorbital arches called the **superciliary ridges** (*arcus superciliares*). The frontal air sinuses are absent at birth, become apparent about the seventh year of life, and from this period until the age of twenty gradually increase in size. Sometimes, however, the sinuses remain very small or never develop at all—or one side may be large and the other small—or one may exist on one side and be absent on the other.¹ The right sinus is usually the larger. These cavities are larger in men than in women. The floor of each sinus is very thin and is over the orbit and the upper border of the lateral mass of the ethmoid. The thinnest portion of the floor is at the upper and inner angle of the orbit, and at this point pus is liable to point in cases of empyema of the sinus. The frontal sinuses are lined by mucous membrane and each sinus communicates with the middle meatus of the nose by the infundibulum. In some cases the sinuses communicate with each other by means of an aperture in the septum and occasionally join the sinus in the crista galli of the ethmoid.²

The **internal surface** (*cerebral surface, facies cerebralis*) of the horizontal portion presents the convex upper surfaces of the orbital plates, separated from each other

¹ Dr. D. Kerfoot Shute. Article on the Skull, in Reference Handbook of the Medical Sciences.

² Ibid.

in the median line by the ethmoidal notch, and marked by eminences and depressions for the convolutions of the frontal lobes of the cerebrum.

The **border** of the horizontal portion is thin, serrated, and articulates with the lesser wing of the sphenoid.

Structure.—The frontal portion and external angular processes consist of diploic tissue surrounded by compact bone. In the frontal sinus region the cancellous tissue is wanting. The horizontal portion is thin, translucent, and composed entirely of compact tissue.

FIG. 46.—Frontal bone at birth. Developed from two lateral halves.

Development (Fig. 46).—The frontal bone is formed in membrane, being developed from *two* primary centres, one for each lateral half, which make their appearance about the seventh or eighth week, above the orbital arches. From this point ossification extends, in a radiating manner, upward into the forehead and backward over the orbit. The nasal spine is developed from two *secondary* centres, while *additional* centres appear in the regions of the internal and external angular processes. Sometimes a centre appears on either side at the lower end of the coronal suture. This latter centre sometimes remains ununited, and is known as the **pterion ossicle**, or it may join with the parietal, sphenoid, or temporal bone. At birth the bone consists of two pieces, which afterward become united,

along the median line, by a suture (metopic) which runs from the vertex to the root of the nose. This suture usually becomes obliterated within a few years after birth, but it occasionally remains throughout life.

Articulations.—With *twelve* bones—two parietal, the sphenoid, the ethmoid, two nasal, two maxillæ, two lacrimal, and two malar.

Attachment of Muscles.—To *three* pairs—the Corrugator supercilii, Orbicularis palpebrarum, and Temporal, on each side.

The Temporal Bone (Os Temporale).

The **temporal bone** consists of three parts—(a) the squamous, (b) the petromastoid, and (c) the tympanic portions—which, though separate in early life, become united in the adult. The three parts meet and form a part of the outer wall and a part of the base of the skull, and of the external auditory meatus.

The Squamous Portion (*squamous temporalis*).—The squamous portion, the anterior and upper part of the bone, is scale-like in form, and is thin and translucent (Fig. 47). Its **external surface** is smooth, convex, and grooved at its back part for the deep temporal arteries; it affords attachment to the Temporal muscle and forms part of the temporal fossa. At its back part may be seen a curved ridge (part of the *temporal ridge*), which serves for the attachment of the temporal fascia, limits the origin of the Temporal muscle, and marks the boundary between the squamous and mastoid portions of the bone. Projecting from the lower part of the squamous portion is a long, arched process of bone, the **zygoma**, or **zygomatic process**. This process is at first directed outward, its two surfaces looking upward and downward; it then appears as if twisted upon itself, and runs forward, its surfaces now looking inward and outward. The superior border of the process is long, thin, and sharp, and serves for the attachment of the temporal fascia. The inferior, short, thick, and arched, has attached to it some fibres of the Masseter muscle. Its outer surface is convex and subcutaneous; its inner is concave, and also affords attachment to the Masseter. The extremity, broad and deeply serrated, articulates with the malar bone.

The zygomatic process is connected to the temporal bone by three divisions, called its **roots**—an anterior, middle, and posterior. The *anterior*, which is short, but broad and strong, is directed inward, to terminate in a rounded eminence, the *eminentia articularis*. This eminence forms the front boundary of the glenoid fossa, and in the recent state is covered with cartilage. The *middle root* (*postglenoid process*) forms the posterior boundary of the *mandibular* portion of the glenoid fossa; while the *posterior root*, which is strongly marked, runs from the upper border of the zygoma, in an arched direction, upward and backward, forming the posterior part of the temporal ridge (*supramastoid crest*). At the junction of the anterior root with the zygoma is a projection, called the **tubercle**, for the attachment of the external lateral ligament of the mandible; and between

FIG. 47.—Left temporal bone. Lateral surface.

the anterior and middle roots is an oval depression, forming part (mandibular) of the glenoid fossa, for the reception of the condyle of the mandible. Between the posterior wall of the external auditory meatus and the posterior root of the zygoma is the area called the **suprameatal triangle** (Macewen), often marked by a spinous process.

The **internal surface** of the squamous portion (Fig. 48) is concave, presents numerous eminences and depressions for the convolutions of the cerebrum, and two well-marked grooves for the branches of the middle meningeal artery.

Borders.—The **superior border** is thin, bevelled at the expense of the internal surface, so as to overlap the lower border of the parietal bone, forming the squamous suture. The **anterior inferior border** is thick, serrated, and bevelled,

alternately at the expense of the inner and outer surfaces, for articulation with the greater wing of the sphenoid.

The Petromastoid Portion (*partes petrosa et mastoidea*).—The petromastoid portion consists of (a) a mastoid portion, the thick conical posterior part behind the external auditory meatus, and (b) a pyramidal portion named the petrous portion, which contains the internal ear and forms part of the floor of the cranial cavity.

FIG. 48.—Left temporal bone. Inner surface.

The Mastoid Portion (*pars mastoidea*).—The mastoid portion is situated at the posterior part of the bone (Figs. 47 and 49).

Surfaces. Outer Surface.—The outer surface of the mastoid is rough, and gives attachment to the Occipitofrontalis and Retrahens aurem (*M. auricularis posterior*) muscles. It is perforated by numerous foramina; one of these, of large size, situated at the posterior border of the bone, is termed the **mastoid foramen** (*foramen mastoideum*); it transmits a vein to the lateral sinus and a small artery from the occipital to supply the dura. The position and size of this foramen are very variable. It is not always present; sometimes it is situated in the occipital bone or in the suture between the temporal and the occipital. The mastoid portion is continued below into a conical projection, the **mastoid process** (*processus mastoideus*), the size and form of which vary somewhat. On the inner side of the mastoid process is a deep groove, the **digastric fossa** (*incisura mastoidea*), for the attachment of the Digastric muscle; and, running parallel with it, but more internal, the **occipital groove** (*sulcus a. occipitalis*), which lodges the occipital artery (*fossa mastoidea*).

Internal Surface.—The internal surface of the mastoid portion presents a deep, curved groove, the **sigmoid fossa**, which lodges part of the lateral sinus; and into it may be seen opening the mastoid foramen, which transmits an emissary vein from the lateral sinus to the posterior auricular or occipital vein and a small artery, the mastoid branch of the occipital artery. A section of the mastoid process (Figs. 49 and 50) shows it to contain a number of cellular spaces, communicating with one another, called the **mastoid cells** (*cellulae mastoideae*), which exhibit the greatest possible variety as to their size and number. At the upper and front part of the bone these cells are large and irregular, and contain air. They diminish in size toward the lower part of the bone; those situated at the apex of the mastoid process are quite small, representing spaces of cancellous bone, and usually containing marrow. Occasionally they are entirely absent, and

FIG. 49.—Section through the petrous and mastoid portions of the temporal bone, showing the communication of the cavity of the tympanum with the mastoid antrum.

the mastoid is solid throughout. In addition to these pneumatic cells may be seen a large, irregular cavity, the **mastoid antrum** (Figs. 49 and 50), situated at the upper and front part of the section. This must be distinguished from the mastoid cells, though it communicates with them. The mastoid cells are not developed until after puberty, but the mastoid antrum is almost as large at birth as it is in the adult bone. The antrum and cells are filled with air, and are lined with a prolongation of the mucous membrane of the tympanum, which extends into them through an opening, by which they communicate with the cavity of the tympanum.

In consequence of the communication which exists between the tympanum and mastoid cells, inflammation of the lining membrane of the former cavity may easily travel backward to that of the antrum, leading to caries and necrosis of their walls and the risk of transference of the inflammation to the lateral sinus or encephalon.

The Petrous Portion (*pars petrosa* [*pyramis*]) (Fig. 48).—The petrous portion is a pyramidal process of bone wedged in at the base of the skull between the sphenoid and occipital bones. Its direction from without is inward, forward, and a little downward. It presents for examination an **apex**, **four surfaces**, and **three borders**, and contains in its interior the essential parts of the organ of hearing.

Apex (*apex pyramidis*).—The apex of the petrous portion, rough and uneven, is received into the angular interval between the posterior border of the greater wing of the sphenoid and the basilar process of the occipital; it presents the anterior or internal orifice of the carotid canal (*foramen caroticum internum*), and forms the posterior and external boundary of the foramen lacerum medium.

FIG. 50.—Right temporal bone cut open. Lateral view of medial half of bone. $\times 2$. (Spalteholz.)

Surfaces.—The **superior surface** of the petrous portion (Fig. 48) forms the posterior part of the middle fossa of the skull; it looks upward and forward. This surface is continuous with the squamous portion, to which it is united by a suture, the **petrosquamous suture**, the remains of which are distinct even at a late period of life.

The superior surface presents six points for examination: (1) An **eminence** (*eminencia arcuata*) near the centre, which indicates the situation of the superior semicircular canal. (2) In front and a little to the outer side of this eminence a depression indicating the position of the tympanum; here the layer of bone which separates the tympanum from the cranial cavity is extremely thin, and is known as the **tegmen tympani**. The thin inferior extremity of this plate drops downward and presents itself at the inner extremity of the Glaserian fissure, there making the fissure double; the anterior slit is called the **canal of Huguier**, and it transmits the chorda tympani nerve. (3) A shallow groove, sometimes double, leading outward and backward to an oblique opening, the **hiatus Fallopii** (*hiatus canalis facialis*), for the passage of the greater petrosal nerve and the petrosal branch of

the middle meningeal artery. (4) A smaller opening (*apertura superior canaliculi tympanici*), occasionally seen external to the latter, for the passage of the smaller petrosal nerve. (5) Near the apex of the bone, the termination of the carotid canal (*foramen caroticum internum*), the wall of which in this situation is deficient in front. (6) Above the canal a shallow depression, the **trigeminal depression** (*impressio trigemini*), for the reception of the Gasserian ganglion.

The **anterior or tympanic surface** is hidden by the tympanic portion of the bone, and is best studied either in very young skulls or in bones which have been cut internal to the tympanic membrane. This surface forms the postero-internal wall of the tympanum and presents an oval foramen (*fenestra ovalis s. vestibuli*), into which the base of the stapes is fitted. Just above and posterior to the fenestra ovalis is the *mastoid antrum*, leading from the tympanum to the mastoid cells. The antrum is roofed by the tegmen tympani. Below and internal to the fenestra ovalis is a rounded eminence, the **promontory**, formed by the first turn of the cochlea. Below the promontory is situated the **fenestra rotunda**, which is closed in the recent state by a membrane.

Above and internal to the fenestra ovalis is the orifice of the canal which transmits the Tensor tympani; below this is the Eustachian canal for the passage of air from the pharynx to the tympanum. The two canals are separated by the *processus cochleariformis*.

The **posterior surface** forms the front part of the posterior fossa of the skull, and is continuous with the inner surface of the mastoid portion of the bone. It presents three points for examination: (1) About its centre a large orifice, the **meatus auditorius internus** (*meatus acusticus internus*), which varies considerably in size; its margins are smooth and rounded, and it leads into a short canal, about one-third inch in length, which runs directly outward and is closed by

FIG. 51.—Diagrammatic view of the fundus of the internal auditory meatus: 1. Falciform crest, 2. Anterior superior cribriform area, 3. Internal opening of the aqueductus Fallopii, 4. Vertical crest which separates the anterior and posterior superior cribriform areas, 5. Posterior superior cribriform area, with (4') openings for nerve filaments, 5'. Anterior inferior cribriform area, 5''. Spirally arranged, sieve-like openings for the nerves to the cochlea, 6. Opening of the central canal of the cochlea, 7. Crest which separates the anterior and posterior inferior cribriform areas, 8. Foramen singulare of Morgagni, with the anterior portion of the canal which gives passage to the nerve to the posterior semicircular canal. (Testut.)

a vertical plate, the **lamina cribrosa**, which is divided by a horizontal crest, the **falciform crest** (*crista falciformis*), into two unequal portions (Fig. 51). Each portion is subdivided by a small vertical crest into two parts, named, respectively, anterior and posterior. The lower portion presents three sets of foramina: one group just below the posterior part of the crest, the **area cribrosa media**, consisting of a number of small openings for the nerves of the saccule; below and posterior to this, the **foramen singulare**, or opening for the nerve of the posterior semicircular canal; in front and below the first, the **tractus spiralis foraminosus**, consisting of a number of small, spirally arranged openings which terminate in the **canalis centralis cochleae** and transmit the nerve of the cochlea; the upper portion, that above the crista, presents behind a series of small openings, the **area cribrosa superior**, for the passage of filaments of the utricle and superior and external semicircular canal, and, in front, one large opening, the commencement of the **aquaeductus Fallopii** (*canalis facialis*), for the passage of the facial nerve. (2) Behind the meatus auditorius is a small slit (*apertura externa aquaeductus vestibuli*), almost hidden by a thin plate of bone, leading to a canal, the **aquaeductus vestibuli**, which transmits the **ductus endolymphaticus**, together with a small

artery and vein. In the interval between these two openings, but above them, is an angular depression (*fossa subarcuata*), which lodges a process of the dura, and transmits a small vein into the cancellous tissue of the bone. In the child this depression is represented by a large fossa, the **floccular fossa**, which extends backward as a blind tunnel under the superior semicircular canal.

The **inferior or basilar surface** (Fig. 52) is rough and irregular, and forms part of the base of the skull. Passing from the apex to the base, this surface presents nine points for examination: (1) A rough surface, quadrilateral in form, which serves partly for the attachment of the Levator palati and Tensor tympani muscles. (2) The large, circular aperture of the carotid canal, the **external carotid foramen** (*foramen caroticum externum*); the canal ascends at first vertically, and then, making a bend, runs horizontally forward and inward; it transmits the internal

FIG. 52.—Petrus portion of the left temporal bone. Inferior surface.

carotid artery and the carotid sympathetic plexus. Within the carotid canal are several openings (*canaliculi caroticotympanici*), which transmit tympanic branches of the internal carotid artery and of the carotid sympathetic plexus. (3) The opening of the **aquaeductus cochleae** (*apertura externa canaliculi cochleae*), a small, triangular opening, lying on the inner side of the latter, close to the posterior border of the petrous portion; it transmits a vein from the cochlea, which joins the internal jugular. (4) Behind these openings a deep depression, the **jugular fossa** (*fossa jugularis*), which varies in depth and size in different skulls; it lodges the lateral sinus, and, with a similar depression on the margin of the jugular process of the occipital bone, forms the foramen lacerum posterius or jugular foramen. (5) A foramen which is the opening of a small canal (*canaliculus tympanicus*) for the passage of Jacobson's nerve (the tympanic branch of the glossopharyngeal); this foramen is seen in front of the bony ridge dividing the

carotid canal from the jugular fossa. (6) A small foramen on the wall of the jugular fossa, for the passage of the articular branch of the vagus (*Arnold's*) nerve. (7) Behind the jugular fossa a smooth, square-shaped facet, the **jugular surface**; it is covered with cartilage in the recent state, and articulates with the jugular process of the occipital bone. (8) The **stylomastoid foramen** (*foramen stylo-mastoideum*), a rather large orifice, placed between the styloid and mastoid processes; it is the termination of the aquaeductus Fallopii, and transmits the facial nerve and stylomastoid artery. (9) The **auricular fissure** (*fissura tympanomastoidea*), situated between the tympanic plate and mastoid process, for the passage of the auricular branch of the vagus nerve. This fissure is the external opening of the *canaliculus mastoideus*, which passes to the aqueduct of Fallopius.

Borders.—The **antero-superior border** (*angulus superior pyramidis*), the longest, is grooved for the superior petrosal sinus, and has attached to it the tentorium cerebelli; at its inner extremity is a semilunar notch, upon which the fifth nerve lies.

The **postero-inferior border** is intermediate in length between the antero-superior and antero-inferior. Its inner half is marked by a groove, which, when completed by its articulation with the occipital, forms the channel for the inferior petrosal sinus. Its outer half presents a deep excavation, the **jugular fossa** (*fossa jugularis*), which, with a similar notch on the occipital, forms the foramen lacerum posterius. A projecting eminence of bone occasionally stands out from the centre of the notch, and divides the foramen into two parts.

The **antero-inferior border** is divided into two parts—an outer, joined to the squamous portion by a suture, the remains of which are distinct; an inner, free, articulating with the spinous process of the sphenoid. At the angle of junction of the petrous and squamous portions is seen the opening of the *canalis musculotubarius*. The antero-inferior border is free and affords attachment to the Tensor tympani and Levator palati muscles.

The Tympanic Portion (*pars tympanica*).—The tympanic portion is placed in front of the anterior surface of the petrous portion; its most internal part is narrow and forms the anterior wall of the Eustachian canal. Externally it broadens out and has an antero-inferior and a postero-superior surface, an antero-superior, an antero-inferior, and an external border. The **antero-inferior surface** looks forward and downward and forms the posterior part of the glenoid fossa. The **postero-superior surface** forms the anterior wall of the external auditory canal. From this surface there continues on to the anterior part of the mastoid portion a U-shaped process, with its concavity upward; this process shares in forming the inferior and posterior wall of the external auditory canal. Between the upturned part of the U-shaped process and the mastoid is a foramen (*fissura tympanomastoidea*) transmitting the tympanic (auricular nerve of Arnold) branch of the vagus. In the concavity of this process is a furrow (*sulcus tympanicus*), in which is placed the tympanic membrane (*membrana tympani*), like a mirror in its frame. The **antero-superior border** fuses with the middle zygomatic root. Internally, this border is continuous with the upper border of the narrow part of the bone, and is separated from the squamous portion of the bone by the Glaserian fissure and a small part of the tegmen tympani. The **antero-inferior border** is thin internally; externally it divides into two laminae and ensheaths the root of the styloid process—hence the name **vaginal process** given to this border. The **external border** is free and rough, and has attached to it the cartilaginous part of the ear.

The **glenoid fossa** (*fossa mandibularis*) is a considerable hollow formed by the squamous part of the temporal, and behind by the tympanic bone. The part of the fossa formed by the squamous portion is covered with cartilage and articulates

with the condyle of the mandible. The posterior part of the fossa lodges part of the parotid gland, and is formed by the antero-inferior surface of the tympanic portion. The fossa is crossed by an oblique fissure, the **petrotympanic fissure** (*Glaserian fissure*), which leads into the tympanum, lodges the processus gracilis of the malleus, and transmits the tympanic branch of the internal maxillary artery. This fissure is closed externally; at its inner extremity it is separated from the squamous portion by the downgrowth of a process of bone from the tegmen tympani (*processus inferior tegmini tympani*) of the petrous portion between the squamous and tympanic plates, making the fissure at its internal extremity a double one. The anterior limb is known as the **canal of Huguier** (*canaliculus chordae tympani*), and transmits the chorda tympani nerve.

The **external auditory meatus** is bounded in front, below, and behind by the tympanic portion. The roof and the upper part of the posterior wall are formed by the squamous portion. The canal is about three-quarters of an inch (18 mm.) in length, and is directed inward and forward. In vertical section it is of oval outline, the long axis of the oval being vertical in the outer segment and oblique in the inner segment.

The **styloid process** is a sharp spine of varying length. It projects downward and forward from the vaginal process of the tympanic part, and gives origin to the stylohyoid and stylomandibular ligaments, and to the Styloglossus, Stylopharyngeus, and Stylohyoid muscles.

Structure.—The squamous portion is like that of the other cranial bones; the mastoid portion, cellular; and the petrous portion, dense and hard.

Development (Fig. 53).—The temporal bone is developed from *ten* centres, exclusive of those for the internal ear and the ossicles—viz., one for the squamous portion, including the zygoma,

FIG. 53.—Development of the temporal bone. From ten centres.

one for the tympanic plate, six for the petrous and mastoid parts, and two for the styloid process. Just before the close of fetal life the temporal bone consists of four parts: (1) The **squamosygomatic** part, ossified in membrane from a single nucleus, which appears at its lower part about the second month. (2) The **tympanic plate**, an imperfect ring, in the concavity of which is a groove, the **sulcus tympanicus**, for the attachment of the circumference of the tympanic membrane. This is also ossified from a single centre, which appears in membrane about the third month. (3) The **petromastoid** part, which is developed from six centres, appearing in the cartilaginous ear capsule about the fifth or sixth month. Four of these are for the petrous portion and are placed around the labyrinth, and two are for the mastoid (Vrolik). According to Huxley, the centres are more numerous and are disposed so as to form three portions: The first portion includes most of the labyrinth (part of the cochlea, vestibule, superior semicircular canals, and the inner wall of the tympanic cavity) and a part of the petrous and mastoid.

This portion he has named the **pro-otic**. The second portion—the **opisthotic**—consists of the rest of the petrous, and is thus made up: the floor of the tympanum, and vestibule surrounds the carotid canal and the outer and lower portions of the cochlea and spread inward below the internal auditory meatus. The third portion—the **pteriatic**—roofs the antrum and tympanic cavity. The fourth portion—the **epi-otic**—includes the remainder of the mastoid. The petromastoid is ossified in cartilage. (4) The **styloid process** is also ossified in cartilage from two centres—one for the base, which appears before birth, and is termed the **tympanohyal**; the other, comprising the rest of the process, is named the **stylohyal**, and does not appear until after birth. Shortly before birth the tympanic plate unites with the squamous. The petrous and mastoid unite with

the squamous during the first year, and the tympanohyal portion of the styloid process about the same time (Figs. 54 and 55). The stylohyal does not join the rest of the bone until after puberty, and in some skulls never becomes united. The subsequent changes in this bone are, that the tympanic plate extends outward and backward, so as to form the **meatus auditorius**. (1) The extension of the tympanic plate, however, does not take place at an equal rate all around the circumference of the ring, but occurs most rapidly on its anterior and posterior portions, and these outgrowths meet and blend, and thus, for a time, there exists in the floor of the meatus a foramen, the **foramen of Huschke**; this foramen, usually closed by the fifth year, may persist throughout life. (2) The glenoid cavity is at first extremely shallow, and looks outward as well as downward; it becomes deeper and is ultimately directed downward. Its change in direction is accounted for as follows: the part of the squamous temporal which supports it lies at first *below* the level of the zygoma. As, however, the base of the skull increases in width, this lower part of the squama is directed horizontally inward to contribute to the middle fossa of the skull, and its surfaces therefore come to look upward and downward. (3) The mastoid portion is at first quite flat, and the stylomastoid foramen and rudimentary styloid process lie immediately behind the tympanic ring. With the development of the air cells the outer part of the mastoid portion grows downward and forward to form the mastoid process, and the styloid process and stylomastoid foramen now come to lie on the under surface. The descent of the foramen is necessarily accompanied by a corresponding lengthening of the aqueduct of Fallopius.

FIG. 54.—Temporal bone at birth. Outer aspect.

FIG. 55.—Temporal bone at birth. Inner aspect.

(4) The downward and forward growth of the mastoid process also pushes forward the tympanic plate, so that the portion of it which formed the original floor of the meatus and containing the foramen of Huschke is ultimately found in the anterior wall. (5) With the gradual increase in size of the petrous portion the floccular fossa or tunnel under the superior semicircular canal becomes filled up and almost obliterated.

Articulations.—With five bones—occipital, parietal, sphenoid, mandible, and malar.

Attachment of Muscles.—To *fifteen*—to the squamous portion, the Temporal; to the zygoma, the Masseter; to the mastoid portion, the Occipitofrontalis, Sternomastoid, Splenius capitis, Trachelomastoid, Digastric, and Posterior auricular; to the styloid process, the Stylopharyngeus, Stylohyoid, and Styloglossus; and to the petrous portion, the Levator palati, Tensor tympani, Tensor palati, and Stapedius.

The Sphenoid Bone (Os Sphenoidale).

The **sphenoid bone** is situated at the anterior part of the base of the skull, articulating with all the other cranial bones, which it binds firmly and solidly together. In its form it somewhat resembles a bat with its wings extended; and is divided into a **central portion** or **body**, two **greater** and two **lesser wings** extending outward on each side of the body, and two processes—the **pterygoid processes**—which project from the lower part of this body.

The Body (corpus).—The body is of large size and hollowed out in its interior so as to form a mere shell of bone. It presents for examination *four* surfaces—a superior, an inferior, an anterior, and a posterior.

Surfaces.—The **superior surface** (*facies cerebralis*) (Fig. 56) presents in front a prominent spine, the **ethmoidal spine**, for articulation with the cribriform plate of the ethmoid; behind this is a smooth surface having in the median line a slight longitudinal eminence, with a depression on each side for the lodgement of the olfactory lobes. This surface is bounded behind by a ridge, which forms the anterior border of a narrow, transverse groove, the **optic groove** (*sulcus chiasmatis*); behind the ridge lies the optic chiasm; the groove is continuous on each side with the **optic foramen** (*foramen opticum*), for the passage of the optic nerve and ophthalmic artery. Behind the optic groove is a small eminence, olive-like in shape, the

FIG. 56—Sphenoid bone. Superior surface.

olivary eminence (*tuberculum sellae*); and still more posteriorly a deep depression, the **sella turcica** (*fossa hypophyseos*), which lodges the circular sinus and the hypophysis. This fossa is perforated by numerous foramina, for the transmission of nutrient vessels into the substance of the bone. It is bounded in front by the **olivary eminence**, and also by two small processes, one on either side, called the **middle clinoid processes** (*processus clinoidei medii*), which are sometimes connected by a spiculum of bone to the anterior clinoid processes. It is bounded behind by a square-shaped plate of bone, the **dorsum sellae**, terminating at each superior angle in a tubercle, the **posterior clinoid process** (*processus clinoideus posterior*). The size and form of these processes vary considerably in different individuals. They deepen the sella turcica, and serve for the attachment of prolongations from the tentorium cerebelli. The sides of the dorsum sellae are notched for the passage of the abducent nerves, and below present a sharp process, the **petrosal process**, which is joined to the apex of the petrous portion of the temporal bone, forming the inner boundary of the middle lacerated foramen. Behind this plate the bone presents a shallow depression, which slopes obliquely backward, and is continuous with the basilar groove of the occipital bone; it is called the **clivus**, and supports the upper part of the pons. On either side of the body is a broad, *f*-shaped groove, which lodges the internal carotid artery and the cavernous sinus; it is called the **carotid** or **cavernous groove** (*sulcus caroticus*).

Along the outer margin of this groove, at its posterior part, is a ridge of bone in the angle between the body and greater wing, called the *lingula* (*lingula sphenoidalis*).

The **posterior surface**, quadrilateral in form, is joined to the basilar process of the occipital bone. During childhood these bones are separated by a layer of cartilage; but later (between the eighteenth and twenty-fifth years) this becomes ossified from above downward, and the two bones then form one piece.

The **anterior surface** (Fig. 57) presents, in the median line, a vertical ridge of bone, the **ethmoidal crest** (*crista sphenoidalis*), which articulates in front with the perpendicular plate of the ethmoid, forming part of the septum of the nose (Fig. 57). On either side of it are irregular openings leading into the **sphenoidal sinuses** (*sinus sphenoidales*), which are two large, irregular cavities of the hollowed out interior of the body of the sphenoid bone, and separated more or less completely from each other by a perpendicular bony septum (*septum sinuum sphenoidalium*). Occasionally they extend into the basilar process of the occipital nearly as far as the foramen magnum. Their form and size vary considerably; they are seldom

FIG. 57.—Sphenoid bone. Anterior surface.¹

symmetrical, and are often partially subdivided by irregular, osseous laminae. One or both sinuses may be absent. The septum is seldom quite vertical, being commonly bent to one or the other side. These sinuses do not exist in very young children, but appear, according to Laurent, in the seventh year. After once appearing they increase in size as age advances. They are partially closed, in front and below, by two thin, curved plates of bone, the **sphenoidal turbinated processes** (*conchae sphenoidales*). At the upper part of each is a round opening (*apertura sinus sphenoidalis*), by which the sinus communicates with the upper and back part of the nose, and occasionally with the posterior ethmoidal cells or sinuses. The lateral margins of the surface present a serrated edge, which articulates with the os planum of the ethmoid, completing the posterior ethmoidal cells; the lower margin, also rough and serrated, articulates with the orbital process of the palate bone, and the upper margin with the orbital plate of the frontal bone.

The **inferior surface** presents, in the middle line, a triangular spine, the **rostrum**

¹ In this figure both the anterior and inferior surfaces of the body of the sphenoid bone are shown, the bone being held with the pterygoid processes almost horizontal.

(*rostrum sphenoidalis*), which is continuous with the sphenoidal crest on the anterior surface, and is received into a deep fissure between the alæ of the vomer. On each side may be seen a projecting lamina of bone, the **vaginal process** (*processus vaginalis*), which runs horizontally inward from near the base of the pterygoid process and articulates with the edges of the vomer. Close to the root of the pterygoid process is a groove (*sulcus pterygopalatinus*), formed into a complete canal when articulated with the sphenoidal process of the palate bone; it is called the **pterygopalatine canal**, and transmits the pterygopalatine vessels and a pharyngeal branch of the sphenopalatine ganglion.

The Greater or Temporal Wings (*alae magna*).—The greater wings are two strong processes of bone which arise from the sides of the body, and are curved in a direction upward, outward, and backward, each being prolonged behind into a sharp-pointed extremity, the **alar**, or **sphenoidal spine** (*spina angularis*). Each wing presents three surfaces and a circumference.

Surfaces.—The **superior surface** (*facies cerebralis*) (Fig. 56) forms part of the middle fossa of the skull; it is deeply concave, and presents eminences and depressions for the convolutions of the cerebrum. At its anterior and internal part is seen a circular aperture, the **foramen rotundum**, for the transmission of the second division of the trigeminal nerve. Behind and external to this is a large oval foramen, the **foramen ovale**, for the transmission of the third division of the trigeminal nerve, the small meningeal artery, and sometimes the small petrosal nerve. At the inner side of the foramen ovale a small aperture may occasionally be seen opposite the root of the pterygoid process; it is the **foramen Vesalii**, transmitting a small vein. In the posterior angle, near to the spine of the sphenoid, is a short canal, sometimes double, the **foramen spinosum**, which transmits the middle meningeal artery. Just to the inner side of the foramen spinosum a minute foramen (*canaliculus innominatum*) is occasionally found, for the passage of the small petrosal nerve.

The **external surface** (Fig. 57) is convex and divided by a transverse ridge, the **pterygoid ridge** (*crista infratemporalis*), into two portions. The superior or larger, convex from above downward, concave from before backward, enters into the formation of the **temporal fossa**, and gives attachment to part of the Temporal muscle. The inferior portion, smaller in size and concave, enters into the formation of the **zygomatic fossa**, and affords attachment to the External pterygoid muscle. It presents, at its posterior part, a sharp-pointed eminence of bone, the **spine**, to which are connected the internal lateral ligament of the mandible and the Tensor palati muscle. At its inner and anterior extremity is a triangular spine of bone, which serves to increase the extent of origin of the External pterygoid muscle.

The **anterior surface** is divided into two parts, the orbital surface above and the sphenomaxillary below. The **orbital surface** is quadrilateral in form; it looks inward and forward, and assists in forming the outer wall of the orbit. It is bounded above by a serrated edge for articulation with the frontal bone. Internally this edge is sharp and free and forms the lower boundary of the sphenoidal fissure. At about the centre of the free part of this border a little tubercle projects, giving origin to one head of the External rectus muscle of the eyeball. At its outer part is a notch for the transmission of a recurrent branch of the lacrimal artery. The **outer border** is serrated for articulation with the malar bone. The **lower border** is rounded and enters into the formation of the sphenomaxillary fissure. This border separates the orbital surface above from the sphenomaxillary portion below. This latter portion is situated just above the pterygoid process and helps to form the posterior wall of the sphenomaxillary fossa in the articulated skull and exhibits the anterior extremity of the foramen rotundum.

Circumference (Fig. 56).—Commencing from behind, that portion of the circumference of the body of the sphenoid to the spine is serrated and articulates by its outer half with the petrous portion of the temporal bone, while the inner half forms the anterior boundary of the middle lacerated foramen, and presents the posterior aperture of the **Vidian canal** (*canalis pterygoideus*) for the passage of the Vidian nerve and artery. In front of the spine, the circumference of the greater wing presents a serrated edge, bevelled at the expense of the inner table below and of the external above, which articulates with the squamous portion of the temporal bone. At the tip of the greater wing a triangular portion is seen, bevelled at the expense of the internal surface, for articulation with the anterior inferior angle of the parietal bone. Internal to this is a triangular, serrated surface, for articulation with the frontal bone; this surface is continuous internally with the sharp inner edge of the orbital plate, which assists in the formation of the sphenoidal fissure, and externally with the serrated margin for articulation with the malar bone.

FIG. 58.—Sphenoid bone. Posterior view.

The Lesser or Orbital Wings (*alae parvae*).—The lesser wings are two thin triangular plates of bone which arise from the upper and lateral parts of the body of the sphenoid, and, projecting transversely outward, terminate in a sharp point (Fig. 56). The **superior surface** of each is smooth, flat, broader internally than externally, and supports part of the frontal lobe of the cerebrum. The **inferior surface** forms the back part of the roof of the orbit and the upper boundary of the **sphenoidal fissure**, or **foramen lacerum anterius** (*fissura orbitalis superior*). This fissure is of a triangular form, and leads from the cavity of the cranium into the orbit. It transmits the third, the fourth, the three branches of the ophthalmic division of the trigeminal, the abducent nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, a recurrent branch from the lacrimal artery to the dura and the ophthalmic vein. The **anterior border** of the lesser wing is serrated for articulation with the frontal bone; the **posterior border**, smooth and rounded, is received into the sylvian fissure of the cerebrum. The inner extremity of this border forms the **anterior clinoid process** (*processus clinoides anterior*). The lesser

wing is connected to the side of the body by two roots, the upper thin and flat, the lower thicker, obliquely directed, and presenting on its outer side, near its junction with the body, a small tubercle, for the attachment of the common tendon of origin of three of the Extrinsic muscles of the eye. Between the two roots is the **optic foramen** (*foramen opticum*), for the transmission of the optic nerve and ophthalmic artery.

The Pterygoid Processes (*processus pterygoidei*).—The pterygoid processes, one on each side, descend perpendicularly from the place where the body and greater wing unite (Fig. 59). Each process consists of an external and an internal lamina or plate, which are joined together by their anterior borders above, but are separated below, leaving an angular cleft, the **pterygoid notch** (*fissura pterygoidea*), in which the pterygoid tuberosity of the palate bone is received. The two plates diverge from each other from their line of connection in front, so as to form in conjunction with the tuberosity of the palate bone a V-shaped fossa, the **pterygoid fossa** (*fossa pterygoidea*). The **external pterygoid plate** (*lamina lateralis processus pterygoidei*) is broad and thin, turned a little outward, and, by its outer surface, forms part of the inner wall of the zygomatic fossa, giving attachment to the External pterygoid; its inner surface forms

FIG. 59.—Sphenoid bone. Posterior surface.

part of the pterygoid fossa, and gives attachment to the Internal pterygoid. The **posterior border** of this plate frequently has one or more rough projections, to one of which is attached the pterygospinous ligament, when this is present. The **internal pterygoid plate** (*lamina medialis processus pterygoidei*) is much narrower and longer, curving outward, at its extremity, into a hook-like process of bone, the **hamular process** (*hamulus pterygoideus*), around which turns the tendon of the Tensor palati muscle. The outer surface of this plate forms part of the pterygoid fossa, the inner surface forming the outer boundary of the posterior aperture of the nares. The posterior border of this plate gives attachment to the pharyngeal aponeurosis throughout its entire length. The Superior constrictor muscle of the pharynx arises from its lower half. Projecting backward from the middle of this border is a spine (*processus tubarius*), which supports the pharyngeal end of the Eustachian tube. Above this the border divides into two lips; the space between is the **scaphoid fossa** (*fossa scaphoidea*). In this fossa arises the Tensor palati muscle. The **anterior margin** articulates with the posterior border of the perpendicular plate of the palate bone.

Superiorly, the internal pterygoid plate has a thin lamina of bone, the **vaginal process**, which runs inward on the under surface of the body of the sphenoid nearly to the rostrum. In the groove between the two in the articulated skull

are seen the alæ of the vomer. On the under surface of the vaginal process is a groove (*sulcus pterygopalatinus*), which in the articulated skull is converted into the pterygopalatal canal by union with the sphenoidal process of the palate bone. At the junction of the vaginal process and the inner plate is the **pterygoid tubercle**, just above which is the posterior opening of the Vidian canal. The anterior surface of the pterygoid process is quite broad at its base, and forms chiefly the posterior wall of the sphenomaxillary fossa.

The Sphenoidal Turbinated Processes (*conchae sphenoidales*).—The sphenoidal turbinated processes are two thin curved plates of bone, which exist as separate pieces until puberty, and occasionally are not joined to the sphenoid in the adult. They are situated at the anterior and interior part of the body of the sphenoid, an aperture (*apertura sinus sphenoidalis*) of variable size being left in the anterior wall of each, through which the sphenoidal sinuses open into the nasal fossæ. They are irregular in form and taper to a point behind, being broader and thinner in front. Their upper surface, which looks toward the cavity of the sinus, is concave; their under surface convex. Each bone articulates in front with the ethmoid, externally with the palate; its pointed posterior extremity is placed above the vomer, and is received between the root of the pterygoid process on the outer side and the rostrum of the sphenoid on the inner.¹

Development.—Up to about the eighth month of fetal life the sphenoid bone consists of two distinct parts—a **posterior** or **postsphenoid** part, which comprises the sella turcica, the greater wings, and the pterygoid processes; and an **anterior** or **presphenoid** part, to which the anterior part of the body and lesser wings belong. It is developed from *fourteen* centres—eight for the postsphenoid division and six for the presphenoid. All parts except the internal pterygoid plates have an intracartilaginous origin.

Postsphenoid Division.—The first nuclei to appear are those for the greater wings (*alisphenoids*). They make their appearance between the foramen rotundum and foramen ovale about the eighth week, and from them the external pterygoid plates are also formed. Soon after, the nuclei for the posterior part of the body appear, one on either side of the sella turcica, and become blended together about the middle of fetal life. About the ninth or tenth week the centre for the internal pterygoid plate appears, followed by the centre for the hamular process; the centre for the lingula appears during the fourth month, and soon joins the rest of the body. The internal and external pterygoid plates become joined at about the sixth month.

FIG. 60.—Plan of development of the sphenoid. From fourteen centres.

FIG. 61.—Sphenoid bone at birth. Posterior aspect.

Presphenoid Division.—The first nuclei to appear are those for the lesser wings (*orbitosphenoids*). They make their appearance about the ninth week, at the outer borders of the optic foramina. A second pair of nuclei appears on the inner side of the foramina shortly after, and, becoming united, form the front part of the body of the bone. The remaining two centres for

¹ A small portion of the sphenoidal turbinated process sometimes enters into the formation of the inner wall of the orbit, between the os planum of the ethmoid in front, the orbital plate of the palate below, and the frontal above.—Cleland, Roy. Soc. Trans., 1862.

the sphenoidal turbinated processes make their appearance about the fifth month. At birth they consist of small triangular laminae, and it is not until the third year that they become hollowed out and cone-shaped. About the fourth year they become fused with the lateral masses of the ethmoid, and between the ninth and twelfth years they unite with the sphenoid bone.

The presphenoid is united to the body of the postsphenoid about the eighth month, so that at birth the bone consists of three pieces—viz., the body in the centre, and on each side the great wings with the pterygoid processes. The lesser wings become joined to the body at about the time of birth. During the first year after birth the greater wings and body are united. From the ninth to the twelfth year the turbinated processes are partially united to the sphenoid, their junction being complete by the twentieth year. Lastly, the sphenoid joins the occipital from the eighteenth to the twenty-fifth year.

Articulations.—The sphenoid articulates with *all* the bones of the cranium, and *five* of the face—the two malar, the two palate, and vomer; the exact extent of articulation with each bone is shown in the accompanying figures.¹

Attachment of Muscles.—To *eleven* pairs—the Temporal, External pterygoid, Internal pterygoid, Superior constrictor, Tensor palati, Levator palpebrae, Superior oblique, Superior rectus, Internal rectus, Inferior rectus, External rectus.

The Ethmoid Bone (*Os Ethmoidale*).

The **ethmoid** is an exceedingly light, spongy bone, of a cubical form, situated at the anterior part of the base of the cranium proper, between the two orbits

at the root of the nose, and contributing to the formation of each of these cavities. It consists of three parts—a **horizontal plate**, which forms part of the base of the cranium proper; a **perpendicular plate**, which forms part of the septum of the nose; and two **lateral masses**, containing a number of spaces.

The **Horizontal Lamina**, or **Cribriform Plate** (*lamina cribrosa*) (Fig. 62), forms part of the anterior fossa of the base of the skull, and is received into the ethmoid notch of the frontal bone between the two orbital plates. Pro-

FIG. 62.—Ethmoid bone Outer surface of right lateral mass. (Enlarged.)

jecting upward from the middle line of this plate is a thick, smooth, triangular process of bone, the **crista galli**. Its *base* joins the cribriform plate. Its *posterior border*, long, thin, and slightly curved, serves for the attachment of the falx cerebri. Its *anterior border*, short and thick, articulates with the frontal bone; and presents two small projecting *alae* (*processus alares*), which are received into corresponding depressions in the frontal, completing the **foramen cecum** behind. Its sides are smooth and sometimes bulging, in which case it is found to enclose a small sinus. On each side of the crista galli the cribriform plate is narrow and deeply grooved, to support the bulb of the olfactory tract, and is perforated by foramina for the passage of the olfactory nerves. These foramina are arranged in three rows: The innermost, which are the largest and least numerous, are lost in grooves on the upper part of the septum; the foramina of the outer row are continued on to the surface of the superior turbinated process. The foramina of the middle row

¹ It also sometimes articulates with the tuberosity of the maxilla.

are the smallest; they perforate the bone and transmit nerves to the roof of the nose. At the front part of the cribriform plate, on each side of the crista galli, is a small fissure, which transmits the nasal branch of the ophthalmic nerve; and at its posterior part a triangular notch, which receives the ethmoidal spine of the sphenoid.

FIG. 63.—Ethmoid bone from behind.

FIG. 64.—Ethmoid bone from above. (Spalteholz.)

The **Vertical Plate** (*lamina perpendicularis*) (Fig. 65) is a thin, flattened, lamella of bone, which descends from the under surface of the cribriform plate, and assists in forming the septum of the nose. It is much thinner in the middle than at the circumference, and is generally deflected a little to one side. Its **anterior border** articulates with the nasal spine of the frontal bone and crest of the nasal bones. Its **posterior border**, divided into two parts, articulates by its upper half with the sphenoidal crest of the sphenoid, by its lower half with the vomer. The **inferior border** serves for the attachment of the triangular cartilage of the nose. On each side of the perpendicular plate numerous grooves are seen, leading from the foramina on the cribriform plate; they lodge filaments of the olfactory nerves.

FIG. 65.—Perpendicular plate of ethmoid (enlarged), shown by removing the right lateral mass.

The **Lateral Mass**, or **Labyrinth** (*labyrinthus ethmoidalis*), of the ethmoid consists of a number of thin-walled cellular cavities, the **ethmoidal cells** (*cellulae ethmoidales*), interposed between two vertical plates of bone, the outer one of which forms part of the orbit, and the inner one part of the outer wall of the nasal fossa of the corresponding side. There are two lateral masses, one on each side. The **ethmoidal cells** are not present at birth, but appear during the fifth year. In the

disarticulated bone many of these cells appear to be broken; but when the bones are articulated they are closed in at every part, except where they open into the nasal fossæ. The **upper surface** of each lateral mass presents a number of apparently half-broken cellular spaces; these are closed in, when articulated, by the edges of the ethmoidal notch of the frontal bone. Crossing this surface are two grooves on each side, converted into canals by articulation with the frontal; they are the **anterior and posterior ethmoidal canals** (*canalis ethmoidale anterior* and *posterior*), and open on the inner wall of the orbit. The **posterior surface** also presents large irregular cellular cavities, which are closed in by articulation with the sphenoidal turbinated processes and the orbital process of the palate. The cells at the anterior surface are completed by the lacrimal bone and nasal process of the maxilla, and those below also by the maxilla.

FIG. 66.—Ethmoid bone. Inner surface of right lateral mass. (Enlarged.)

The **outer surface** of each lateral mass consists chiefly of a thin, smooth, oblong plate of bone, called the **os planum** (*lamina papyracea*); it forms part of the inner wall of the orbit, and articulates, *above*, with the orbital plate of the frontal; *below*, with the maxilla; in *front*, with the lacrimal; and *behind*, with the sphenoid and orbital process of the palate. In front of the os planum are found the **anterior ethmoidal cells**, which are completed by the lacrimal bone and the nasal process of the maxilla.

From the inferior part of each lateral mass, immediately beneath the os planum, there projects downward and backward an irregular hook-like lamina of bone, called the **unciform process** (*processus uncinatus*); it serves to close in the upper part of the orifice of the antrum (Fig. 71), and articulates with the ethmoidal process of the turbinated bone. It is often broken in disarticulating the bones.

The **inner surface** of each lateral mass forms part of the outer wall of the nasal fossa of the corresponding side. It is formed of a thin lamella of bone, which descends from the under surface of the cribriform plate, and terminates below in a free, convoluted margin, the **middle turbinated process** (*concha nasalis media*). The whole of this surface is rough and marked above by numerous grooves, which run nearly vertically downward from the cribriform plate; they lodge branches of the olfactory nerve, which are distributed on the mucous membrane covering the bone. The back part of this surface is subdivided by a narrow oblique fissure, the **superior meatus of the nose** (*meatus nasi superior*), bounded above by a thin, curved plate of bone, the **superior turbinated process** (*concha nasalis superior*). By means of an orifice at the upper part of this fissure the posterior ethmoidal cells open into the superior meatus. Below, and in front of the superior meatus, is seen the convex surface of the middle turbinated process. It extends along the whole length of the inner surface of each lateral mass; its lower margin is free and thick, and its concavity, directed outward, assists in forming the middle meatus.¹ It is by a large orifice at the upper and front part of the middle meatus that the anterior ethmoidal cells, and through them the frontal sinuses, communicate with the nose by means of a funnel-shaped canal, the **infundibulum** (*infundibulum ethmoidale*). The cellular cavities of each lateral mass, thus walled in by the os planum in the outer side and by the other bones already mentioned, are divided by

¹ In 9 per cent. of specimens examined, Lothrop found that the ethmoidal cells were completed by the middle turbinated processes.

a thin transverse bony partition into two sets, which do not communicate with each other; they are termed the **anterior** and **posterior ethmoidal sinuses**. The former, more numerous, communicate with the frontal sinuses above and the middle meatus below by means of the infundibulum; the posterior, less numerous, open into the superior meatus and communicate (occasionally) with the sphenoidal sinuses. In some cases the ethmoidal sinuses communicate with the maxillary sinus. In some cases the os planum never develops, and the ethmoidal sinuses are separated from the orbit merely by membrane.

Development.—The ethmoid is developed in cartilage from *three* centres—one for the perpendicular lamella, and one for each lateral mass. The lateral masses are first developed, ossific granules making their appearance in the os planum between the fourth and fifth months of fetal life, and extending into the turbinated processes. At birth the bone consists of the two lateral masses, which are small and poorly developed. During the first year after birth the perpendicular plate and crista galli begin to ossify, from a single centre, and become joined to the lateral masses about the beginning of the second year. The cribriform plate is ossified partly from the perpendicular plate and partly from the lateral masses. The formation of the ethmoidal cells, which completes the bone, does not commence until the end of the fourth year.

Articulations.—With *thirteen* bones—the sphenoid, the frontal, and eleven of the face, the two nasal, two palate, two maxillæ, two lacrimal, two turbinated, and the vomer. *No muscles* are attached to this bone.

THE BONES OF THE FACE (OSSA FACIÆ).

The **facial bones** are fourteen in number—viz., the

Two nasal.
Two maxillæ.
Two lacrimal.
Two malar.

Two palate.
Two turbinated.
Vomer.
Mandible.

The Nasal Bones (Ossa Nasalia).

The **nasal bones** are two small oblong bones, varying in size and form in different individuals; they are placed side by side at the middle and upper part of the face, forming by their junction “the bridge” of the nose (Fig. 67). Each bone presents for examination two surfaces and four borders.

Surfaces.—The **outer surface** is concave from above downward, convex from side to side; it is covered by the *Pyramidalis* and *Compressor nasi* muscles. It is marked by numerous small arterial furrows, and perforated about its centre by a foramen (*foramen nasale*), sometimes double, for the transmission of a small vein.

The **inner surface** is concave from side to side, convex from above downward, in which direction it is traversed by a longitudinal groove (sometimes a canal), for the passage of a branch of the nasal nerve.

Borders.—The **superior border** is narrow, thick, and serrated, for articulation with the nasal notch of the frontal bone.

The **inferior border** is broad, thin, sharp, inclined obliquely downward, outward, and backward, and serves for the attachment of the lateral cartilage of the nose. This border presents, about its middle, a notch, through which passes the branch of the nasal nerve above referred to, and is prolonged at its inner extremity into a sharp spine, which, when articulated with the opposite bone, forms the **nasal angle**.

The **external border** is serrated, bevelled at the expense of the internal surface above and of the external below, to articulate with the nasal process of the maxilla.

FIG. 67.—Nasal and lacrimal bones in situ.

FIG. 68.—Right nasal bone.

FIG. 69.—Left nasal bone.

The **internal border**, thicker above than below, articulates with its fellow of the opposite side, and is prolonged behind into a vertical crest, which forms part of the septum of the nose; this crest articulates from above downward with the nasal spine of the frontal, the perpendicular plate of the ethmoid, and the triangular septal cartilage of the nose.

Development.—Of intramembranous origin and from *one* centre for each bone, which appears about the eighth week.

Articulations.—With *four* bones—two of the cranium, the frontal and ethmoid, and two of the face, the opposite nasal and the maxilla.

The nasal bone has *no muscles* attached to it.

The Maxillæ (Upper Jaw).

The **maxillæ** are the largest bones of the face, excepting the mandible, and form, by their union, the whole of the upper jaw. Each maxilla assists in the formation of the walls of three cavities, the roof of the mouth, the floor and outer wall of the nasal fossæ, and the floor of the orbit, and also enters into the formation of two fossæ, the zygomatic and sphenomaxillary, and two fissures, the sphenomaxillary and pterygomaxillary. The bone presents for examination a body and four processes—malar, nasal, alveolar, and palatal.

The Body (*corpus maxillae*).—The body is somewhat cuboid and is hollowed out in its interior to form a large cavity, the **antrum of Highmore** (*sinus maxillaris*). Its surfaces are four—an external or facial, a posterior or zygomatic, a superior or orbital, and an internal or nasal.

Surfaces.—The **facial surface** (*facies anterior*) (Fig. 70) is directed forward and outward. It presents at its lower part a series of eminences corresponding to the position of the anterior five teeth. Just above those for the incisor teeth is a depression, the **incisive fossa**, which gives origin to the Depressor alae nasi; and below it to the alveolar border is attached a slip of the Orbicularis oris. Above and a little external to it the Compressor naris arises. More external is another depression, the **canine fossa** (*fossa canina*), larger and deeper than the incisive fossa, from which it is separated by a vertical ridge, the **canine eminence**, corresponding to the socket of the canine tooth. The canine fossa gives origin to the Levator anguli oris. Above the canine fossa is the **infraorbital foramen** (*foramen infraorbitale*),

Outer Surface.

FIG. 70.—Left maxilla. Outer surface.

the termination of the infraorbital canal; it transmits the infraorbital vessels and nerve. Sometimes the infraorbital canal opens by two, very rarely by three, orifices on the face. Above the infraorbital foramen is the **margin of the orbit** (*margo infraorbitalis*), which affords partial attachment to the Levator labii superioris proprius. To the sharp margin of bone which bounds this surface in front and separates it from the internal surface is attached the Dilator naris posterior.

The **posterior** (*facies infratemporalis*) or **zygomatic surface** is convex, directed backward and outward, and forms part of the **zygomatic fossa**. It is separated from the facial surface by a strong ridge of bone, the **malar process**, which extends upward from the socket of the second molar tooth. It presents about its centre several apertures leading to canals in the substance of the bone; they are termed the **posterior dental canals** (*foramina alveolaria*), and transmit the posterior dental vessels and nerves. At the lower part of this surface is a

rounded eminence, the **maxillary tuberosity** (*tuber maxillare*), especially prominent after the growth of the wisdom tooth, rough on its inner side for articulation with the tuberosity of the palate bone, and sometimes with the external pterygoid plate. It gives attachment to a few fibres of origin of the Internal pterygoid muscle. Immediately above this is a smooth surface, which forms the anterior boundary of the sphenomaxillary fossa; it presents a groove which, running obliquely downward, is converted into a canal by articulation with the palate bone, forming the **posterior palatine** or **palatomaxillary canal** for the descending palatine artery and great palatine nerve.

The **superior or orbital surface** (*facies orbitalis*) is thin, smooth, triangular, and forms part of the floor of the orbit. It is bounded internally by an irregular margin, which in front presents a notch, the **lacrimal notch** (*incisura lacrimalis*), which receives the lacrimal bone; in the middle it articulates with the os planum of the ethmoid, and behind with the orbital process of the palate bone; bounded externally by a smooth, rounded edge which enters into the formation of the sphenomaxillary fissure, and which sometimes articulates at its anterior extremity with the orbital plate of the sphenoid; bounded in front by part of the circumference of the orbit, which is continuous on the inner side with the nasal, on the outer side with the malar process. Along the middle line of the orbital surface is a deep groove, the **infraorbital groove** (*sulcus infraorbitalis*), for the passage of the infraorbital vessels and nerve. The groove commences at the middle of the outer border of this surface, and, passing forward, terminates in a canal, which subdivides into two branches. One of the canals, the **infraorbital canal**, opens just below the margin of the orbit; the other, which is smaller, runs downward in the substance of the anterior wall of the antrum; it is called the **anterior dental canal**, and transmits the anterior dental vessels and nerve to the front teeth of the maxilla. From the back part of the infraorbital canal a second small canal is sometimes given off, which runs downward in the outer wall of the antrum, and conveys the middle dental nerve to the bicuspid teeth. Occasionally this canal is a branch of the anterior dental canal.

At the inner and fore part of the orbital surface, just external to the lacrimal groove for the nasal duct, is a depression which gives origin to the Inferior oblique muscle of the eye.

The **internal surface** (Fig. 71) is unequally divided into two parts by a horizontal projection of bone, the **palatal process** (*processus palatinus*); the portion above the palatal process is known as the **nasal surface** (*facies nasalis*). It forms part of the outer wall of the nasal fossa. Below the palate process is the cavity of the mouth. The superior division of the nasal surface presents a large, irregular opening, the **maxillary hiatus** (*hiatus maxillaris*), leading into the maxillary sinus. At the upper border of this aperture are numerous broken cellular cavities, which in the articulated skull are closed by the ethmoid and lacrimal bones. Below the aperture is a smooth concavity which forms part of the inferior meatus of the nasal fossa, and behind it is a rough surface which articulates with the perpendicular plate of the palate bone, traversed by a groove which, commencing near the middle of the posterior border, runs obliquely downward and forward, and forms, when completed by its articulation with the palate bone, the **posterior palatine** or **palatomaxillary canal**. In front of the opening of the antrum is a deep groove, converted into a canal (*canalis nasolacrimalis*) by the lacrimal and turbinated bones. The groove is called the **lacrimal groove** (*sulcus lacrimalis*), and lodges the nasal duct. More anteriorly is a well-marked rough ridge, the **inferior turbinated crest** (*crista conchal*), for articulation with the turbinated bone. The shallow concavity above this ridge forms part of the middle meatus of the nose, while that below it forms part of the inferior meatus. The portion of this surface below the palatal process is concave, rough, and uneven, and

perforated by numerous small foramina for the passage of nutrient vessels. It enters into the formation of the roof of the mouth.

The **antrum of Highmore** (*sinus maxillaris*) is a pyramidal cavity hollowed out of the body of the maxilla. It varies much in size. It is in most cases a large cavity, but in some is very small. The apex of the antrum, directed outward, is formed by the malar process; its base by the outer wall of the nose. Its walls are everywhere exceedingly thin, and correspond to the orbital, facial, and zygomatic surfaces of the body of the bone. The floor is formed by the alveolar process of the maxilla. The roof corresponds to the orbital plate. Its inner wall, or base, presents, in the disarticulated bone, a large, irregular aperture (*hiatus maxillaris*), which communicates with the nasal fossa. The margins of this aperture are thin and ragged, and the aperture itself in the articulated skull is much con-

FIG. 71.—Left maxilla. Internal surface.

tracted by its articulation with the ethmoid above, the turbinated bone below, and the palate bone behind.¹ In the articulated skull this cavity communicates with the middle meatus of the nasal cavity, generally by two small apertures left between the above-mentioned bones. In the recent state usually only one small opening exists, near the upper part of the cavity, sufficiently large to admit the end of a probe, the other being closed by the lining membrane of the sinus.

Crossing the cavity of the antrum are often seen several projecting laminae of bone, similar to those seen in the sinuses of the cranium; on its posterior wall are the posterior dental canals, transmitting the posterior dental vessels and nerves to the teeth. Projecting into the floor are several conical processes, corresponding to the roots of the first and second molar teeth; in some cases the floor is perforated by the teeth in this situation; projecting into the antrum from the roof is a ridge corresponding to the infraorbital canal.

¹ In some cases, at any rate, the lacrimal bone encroaches slightly on the anterior superior portion of the opening, and assists in forming the inner wall of the antrum.

The Processes.—The **malar process** (*processus zygomaticus*) is a rough, triangular eminence, situated at the angle of separation of the facial from the zygomatic surface. In front it is concave, forming part of the facial surface; behind it is also concave, and forms part of the zygomatic fossa; above it is rough and serrated for articulation with the malar bone; while below a prominent ridge marks the division between the facial and zygomatic surfaces. A small part of the Masseter muscle arises from this process.

The **nasal process** (*processus frontalis*) is a strong, triangular plate of bone, which projects upward, inward, and backward by the side of the nose, forming part of its lateral boundary. Its *external surface* is concave, smooth, perforated by numerous foramina, and gives attachment to the Levator labii superioris alaeque nasi, the Orbicularis palpebrarum, and the Tendo oculi. Its *internal surface* forms part of the outer wall of the nasal fossa; at its upper part it presents a rough, uneven surface, which articulates with the ethmoid bone, closing in the anterior ethmoidal cells; below this is a transverse ridge, the **superior turbinated crest** (*crista ethmoidalis*), for articulation with the middle turbinated process of the ethmoid; below the crest is a shallow, smooth concavity which forms part of the middle meatus; below this again is the inferior turbinated crest (already described), where the process joins the body of the bone. Its *upper border* articulates with the frontal bone. The *anterior border* of the nasal process is thin, directed obliquely downward and forward, and presents a serrated edge for articulation with the nasal bone; its *posterior border* is thick, and hollowed into a groove, the **lacrimal groove** (*sulcus lacrimalis*), for the nasal duct; of the two margins of this groove, the inner one articulates with the lacrimal bone, the outer one forms part of the circumference of the orbit. Just where the latter joins the orbital surface is a small tubercle, the **lacrimal tubercle**; this serves as a guide to the position of the lacrimal sac in the operation for lacrimal fistula. The lacrimal groove in the articulated skull is converted into a canal (*canalis lacrimalis*) by the lacrimal bone and lacrimal process of the turbinated bone; it is directed downward, and a little backward and outward, is about the diameter of a goose-quill, slightly narrower in the middle than at either extremity, and terminates below in the inferior meatus. It lodges the nasal duct.

The **alveolar process** (*processus alveolaris*) is the thickest and most spongy part of the bone, broader behind than in front, and excavated into deep cavities for the reception of the teeth (*alveoli dentales*). These cavities are eight in number, and vary in size and depth according to the teeth they contain. That for the canine tooth is the deepest; those for the molars are the widest, and subdivided into minor cavities by septa; those for the incisors are single, but deep and narrow. The Buccinator muscle arises from the outer surface of this process as far forward as the first molar tooth. After the loss of the prominent teeth at any time, but especially in old age, this process, like that of the mandible, is absorbed.

The **palatal process** (*processus palatinus*), thick and strong, projects horizontally inward from the inner surface of the bone. It is much thicker in front than behind, and forms a considerable part of the floor of the nostril and the roof of the mouth. Its *inferior surface* (Fig. 72) is concave, rough and uneven, contains numerous little cavities for the glands of the mucous membrane, and forms part of the roof of the mouth. This surface is perforated by numerous foramina for the passage of the nutrient vessels, channelled at the back part of its alveolar border by a longitudinal groove, sometimes a canal, for the transmission of the posterior palatine vessels, and the great posterior palatine nerve from Meckel's ganglion, and presents little depressions for the lodgement of the palatine glands. When the two maxillæ are articulated, a large fossa may be seen in the middle line, immediately behind the incisor teeth. This is the **anterior palatine fossa**. On examining the bottom of this fossa four canals are seen: two branch off

laterally to the right and left nasal fossæ, and two—one in front and one behind—lie in the middle line. The former pair of these openings are named the **incisor foramina**, or **foramina of Stenson**; they are the openings of the forking **incisor canal**, through which pass the anterior or terminal branches of the descending or posterior palatine arteries, which ascend from the mouth to the nasal fossæ, and they contain the remains of Jacobson's organ. The canals in the middle line are termed the **foramina of Scarpa**, and transmit the nasopalatine nerves, the left passing through the anterior, and the right through the posterior, canal. Occasionally in adults' skulls, often in children's skulls, on the palatal surface of the process a delicate linear suture may sometimes be seen extending from the anterior palatine fossa to the interval between the lateral incisor and the canine tooth. This marks out the **premaxillary bones** (*os incisivum*) on each side, and includes the whole thickness of the alveolus, the corresponding part of the floor of the nose, and the anterior nasal spine, and contains the sockets of the incisor teeth; in some animals it exists as a separate bone. The **upper surface** of the palatal process is concave from side to side, smooth, and forms part of the floor of the nose. It presents the upper orifices of the foramina of Stenson and Scarpa, the former being on each side of the middle line, the latter being situated in the intermaxillary suture, and therefore not visible unless the two bones are placed in apposition. The **outer border** of the palatal process is incorporated with the rest of the bone. The **inner border** is thicker in front than behind, and is raised above into a ridge, the **nasal crest** (*crista nasalis*), which, with the corresponding ridge in the opposite bone, forms a groove for the reception of the vomer. In front this crest rises to a considerable height, and this portion is named the **incisor crest**. The **anterior margin** is bounded by the thin, concave border of the opening of the nose, prolonged forward internally into a sharp process, forming, with a similar process of the opposite bone, the **anterior nasal spine** (*spina nasalis anterior*). The **posterior border** is serrated for articulation with the horizontal plate of the palate bone.

FIG. 72.—The palate and alveolar arch.

Development.—This bone commences to ossify at a very early period, and ossification proceeds in it with great rapidity, so that it is difficult to ascertain with certainty its precise number of centres. It appears, however, probable that it is ossified from *six* centres, which develop in membrane: (1) One, the *orbitonasal*, which forms that portion of the body of the bone which lies internal to the infraorbital canal, including the floor of the orbit, the outer wall of the nasal fossa, and the nasal process. (2) A *malar*, which gives origin to that portion of the bone which lies external to the infraorbital canal and the malar process. (3) A *palatal*, from which is developed the palatal process posterior to Stenson's canal and the

adjoining part of the nasal wall. 4. A *premaxillary*, for the front part of the alveolus, which carries the incisor teeth and corresponds to the premaxillary bone of the lower animals. (5) A *nasal*, that gives rise to the nasal process and the portion above the canine tooth. (6) An *infravomerine*, that lies beneath the vomer and between the palatal and premaxillary centres. The premaxillary centre is in close association with the development of the perpendicular plate of the ethmoid and the vomer. According to Albrecht it develops from two centres of ossification, each having an

Anterior Surface.

Inferior Surface.

FIG. 73.—Development of the maxillæ. At birth.

incisive tooth. The one possessing the mesal segment he calls the *endognathion*. The lateral segment he calls the *mesognathion*, while to the maxilla he gives the name *exognathion*. These segments are separated by five sutures. The failure of union of any of these segments will lead to the various forms of cleft palate. These centres appear about the eighth week, and by the tenth week have become fused together so that the bone consists of two portions, one the maxilla proper, and the other the premaxillary portion. The suture between these two portions on the palate persists until middle life, but is not to be seen on the facial surface. This is believed by Callender to be due to the fact that the front wall of the sockets of the incisive teeth is not formed by the premaxillary bone, but by an outgrowth from the facial part of the maxilla. The antrum appears as a shallow groove on the inner surface of the bone at an earlier period than any of the other nasal sinuses, its development commencing about the fourth month of fetal life, and reaches its full size after the second dentition. The sockets for the teeth are formed by the growing downward of two plates from the dental groove, which subsequently becomes divided by partitions jutting across from the one to the other. If the two palatal processes fail to unite partially or completely, a partial or complete cleft palate results.

Articulations.—With *nine* bones, two of the cranium, the frontal and ethmoid, and seven of the face—viz., the nasal, malar, lacrimal, turbinated, palate, vomer, and its fellow of the opposite side. Sometimes it articulates with the orbital plate of the sphenoid, and sometimes with its external pterygoid plate.

Attachment of Muscles.—To *twelve*—the Orbicularis palpebrarum, Obliquus oculi inferior, Levator labii superioris alaeque nasi, Levator labii superioris proprius, Levator anguli oris, Compressor naris, Depressor alae nasi, Dilator naris posterior, Masseter, Buccinator, Internal pterygoid, and Orbicularis oris.

Applied Anatomy.—It is from the extreme thinness of the walls of the antrum that we are enabled to explain how a tumor growing from the antrum encroaches upon the adjacent parts, pushing up the floor of the orbit and displacing the eyeball, projecting inward into the nose, protruding forward on to the cheek, and making its way backward into the zygomatic fossa and downward into the mouth.

CHANGES PRODUCED IN THE UPPER JAW BY AGE.

At birth and during infancy the diameter of the bone is greater in an antero-posterior than in a vertical direction. Its nasal process is long, its orbital surface large, and its tuberosity well marked. In the adult the vertical diameter is the greater, owing to the development of the alveolar process and the increase in size of the antrum. In old age the bone approaches again in character to the infantile condition; its height is diminished, and after the loss of the teeth the alveolar process is absorbed, and the lower part of the bone contracted and diminished in thickness.

The Lacrimal Bone (Os Lacrimale).

The **lacrimal** (*lacrima*, a tear) is the smallest and most fragile bone of the face. There are two lacrimal bones. They are situated at the front part of the inner wall of the orbit (Fig. 67), and resemble somewhat in form, thinness, and size a finger nail; hence, they are termed the *ossa unguis*. Each bone presents for examination two surfaces and four borders.

Surfaces.—The **external or orbital surface** (Fig. 74) is divided by a vertical ridge, the **lacrimal crest** (*crista lacrimonalis posterior*), into two parts. The portion

of bone in front of this ridge, the **lacrimal sulcus** (*sulcus lacrimalis*), presents a smooth, concave, longitudinal groove, the free margin of which unites with the nasal process of the maxilla, completing the **lacrimal canal**. The upper part of this groove (*fossa sacci lacrimalis*) lodges the lacrimal sac; the lower part (*sulcus lacrimalis*) lodges the nasal duct. The portion of bone behind the ridge is smooth, slightly concave, and forms part of the inner wall of the orbit. The ridge, with a part of the orbital surface immediately behind it, affords origin to the Tensor tarsi muscle; it terminates below in a small, hook-like projection, the **hamular process** (*hamulus lacrimalis*), which articulates with the lacrimal tubercle of the maxilla and completes the upper orifice of the lacrimal groove. It sometimes exists as a separate piece, which is then called the **lesser lacrimal bone**.

The **internal or nasal surface** presents a depressed furrow, corresponding to the ridge on its outer surface. The surface of bone in front of this forms part of the middle meatus, and that behind it articulates with the ethmoid bone, closing in the anterior ethmoidal cells.

Borders.—Of the four borders, the **anterior** is the longest, and articulates with the nasal process of the maxilla. The **posterior**, thin and uneven, articulates with the os planum of the ethmoid. The **superior**, the shortest and thickest, articulates with the internal angular process of the frontal bone. The **inferior** is divided by the lower edge of the vertical crest into two parts; the posterior part articulates with the orbital plate of the maxilla; the anterior portion is prolonged downward into a pointed process, which articulates with the lacrimal process of the turbinated bone and assists in the formation of the lacrimal canal.

FIG. 74.—Left lacrimal bone. External surface. (Slightly enlarged.)

Development.—From a single centre, which makes its appearance in membrane at about the eighth or ninth week.

Articulations.—With four bones—two of the cranium, the frontal and ethmoid, and two of the face, the maxilla and the turbinated.

Attachment of Muscles.—To one muscle, the Tensor tarsi.

The Malar Bone (Os Zygomaticum).

The **malar bone** is a quadrangular bone, situated at the upper and outer part of the face. It forms the prominence of the cheek, part of the outer wall and floor of the orbit, and part of the temporal and zygomatic fossæ (Fig. 75). Each bone presents for examination an external and an internal surface; four processes, the frontal, orbital, maxillary, and zygomatic processes; and four borders.

Surfaces.—The **external surface** (*facies malaris*) (Fig. 76) is smooth, convex, perforated near its centre by a small aperture, the **malar foramen** (*foramen zygomaticofaciale*), for the passage of nerves and vessels from the orbit. The malar surface is covered by the Orbicularis palpebrarum muscle, and affords attachment to the Zygomaticus major and minor muscles.

The **internal surface** (*facies temporalis*) (Fig. 77), directed backward and inward, is concave, presenting anteriorly a rough, triangular surface, for articulation with the maxilla; and behind, a smooth concave surface, which above forms the anterior boundary of the temporal fossa, and below, where it is wider, forms part of the zygomatic fossa. This surface presents, a little above its centre, the aperture of a **malar canal** (*foramen zygomaticotemporale*), and affords attachment at its lower part to a portion of the Masseter muscle.

Processes.—The **frontal process** (*processus frontosphenoidalis*) is thick and serrated, and articulates with the external angular process of the frontal bone. To its orbital margin is attached the external tarsal ligament.

FIG. 75.—Right malar bone in situ.

The **orbital process** is a thick and strong plate, which projects backward from the orbital margin of the bone. Its *supero-internal surface* (*facies orbitalis*), smooth and concave, forms, by its junction with the orbital surface of the maxilla and with the greater wing of the sphenoid, part of the floor and outer wall of the orbit. Its *temporal surface*, smooth and concave, forms part of the zygomatic and temporal

FIG. 76.—Left malar bone. Outer surface.

FIG. 77.—Left malar bone. Inner surface.

fossæ. Its *anterior margin* is smooth and rounded, forming part of the circumference of the orbit. Its *superior margin*, rough and directed horizontally, articulates with the frontal bone behind the external angular process. Its *posterior margin* is rough and serrated for articulation with the sphenoid; *internally* it is also serrated for articulation with the orbital surface of the maxilla. At the

angle of junction of the sphenoidal and maxillary portions a short, rounded, non-articular margin is generally seen; this forms the anterior boundary of the sphenomaxillary fissure; occasionally no such nonarticular margin exists, the fissure being completed by the direct junction of the maxilla and sphenoid bones or by the interposition of a small Wormian bone in the angular interval between them. On the *supero-internal surface* of the orbital process are seen a single or double **temporomalar foramen** (*foramen zygomaticoorbitale*), the entrance of the temporomalar canal. This canal may be bifurcated, or there may be two canals from the beginning; one of these usually opens on the posterior surface, the other (occasionally two) on the facial surface; they transmit filaments (**temporomalar**) of the orbital branch of the superior maxillary nerve.

The **zygomatic process** (*processus temporalis*), long, narrow, and serrated, articulates with the zygomatic process of the temporal bone.

Borders.—The **antero-superior** (*orbital border*) is smooth, arched, and forms a considerable part of the circumference of the orbit. The **antero-inferior** or **maxillary border** is rough, and bevelled at the expense of its inner table, to articulate with the maxilla, affording attachment by its margin to the Levator labii superioris proprius, just at its point of junction with the maxilla. The **postero-superior** (*temporal border*) curved like an italic letter *f*, is continuous above with the commencement of the temporal ridge; below, with the upper border of the zygomatic arch; it affords attachment to the temporal fascia. The **postero-inferior** (*masseteric border*) is continuous with the lower border of the zygomatic arch, affording attachment by its rough edge to the Masseter muscle.

Development.—The malar bone ossifies generally from *three* centres, which appear about the eighth week—one for the zygomatic and two for the orbital portion—and which fuse about the fifth month of fetal life. The bone is sometimes, after birth, seen to be divided by a horizontal suture into an upper and larger and a lower and smaller division. In some primates the malar bone consists of two parts, an orbital and a malar.

Articulations.—With *four* bones—three of the cranium, frontal, sphenoid, and temporal; and one of the face, the maxilla.

Attachment of Muscles.—To *four*—the Levator labii superioris proprius, Zygomaticus major and minor, and Masseter.

The Palate Bone (Os Palatinum).

The **palatal bones**¹ are situated at the back part of the nasal fossæ; they are wedged in between the maxilla and the pterygoid processes of the sphenoid (Fig. 78). Each bone assists in the formation of three cavities—the floor and outer wall of the nose, the roof of the mouth, and the floor of the orbit—and enters into the formation of two fossæ, the **sphenomaxillary** (*fossa pterygopalatina*) and **pterygoid fossæ** (*fossa pterygoidea*); and one fissure, the **sphenomaxillary fissure** (*fissura orbitalis inferior*). In form the palate bone somewhat resembles the letter L, and may be divided into an inferior or horizontal plate and a superior or vertical plate.

The **Horizontal Plate** (*pars horizontalis*) (Figs. 79 and 80) is of a quadrilateral form, and presents two surfaces and four borders.

Surfaces.—The **superior** or **nasal surface** (*facies nasalis*), concave from side to side, forms the back part of the floor of the nasal cavity.

The **inferior** or **palatine surface** (*facies palatina*), slightly concave and rough, forms the back part of the hard palate. At its posterior part may be seen a transverse ridge, more or less marked, for the attachment of part of the aponeurosis of the

¹ The word *palate* is frequently used as an adjective. *Palatal* is the correct form (from *palatum*, the palate), but usage sanctions *palatine* in certain compounds, despite the fact that palatine is derived from *palatium*, a palace. This is another example of what is charitably called a "late Latin" form, akin to *halluz* and *hallucis*. —[Editor.]

Tensor palati muscle. At the outer extremity of this ridge is a deep groove, the **pterygopalatine groove** (*sulcus pterygopalatinus*), converted into a canal by its articulation with the tuberosity of the maxilla, and forming the lower end of the **posterior palatine canal** (*canalis pterygopalatinus*). Near this groove the orifices (*foramina palatina minora*) of one or two small canals, **accessory posterior palatine canals** (*canales palatini*) may be seen. Through the posterior palatine canal emerge the descending palatine artery and the great posterior palatine nerve.

Borders.—The **anterior** is serrated, bevelled at the expense of its inferior surface, and articulates with the palatal process of the maxilla. The **posterior** is concave, free, and serves for the attachment of the soft palate. Its inner extremity is sharp and pointed, and when united with the opposite bone forms a

FIG. 78.—Internal surface of left maxilla.

projecting process, the **palatine spine** (*spina nasalis posterior*), for the attachment of the Azygos uvulae muscle. The **external** is united with the lower part of the perpendicular plate almost at right angles. The **internal**, the thickest, is serrated for articulation with its fellow of the opposite side; its superior edge is raised into a ridge, which, united with the opposite bone, forms a **crest** (*crista nasalis*), into which the vomer is received.

The **Vertical or Perpendicular Plate** (*pars perpendicularis*) (Figs. 79 and 80) is thin, of an oblong form, and directed upward and a little inward. It presents two surfaces, an external and an internal, and three borders.

Surfaces.—The **internal, medial, or nasal surface** (*facies nasalis*) presents at its lower part a broad, shallow depression, which forms part of the **inferior meatus** of the nose. Immediately above this is a well-marked ridge, the **inferior turbinated crest** (*crista conchalis*), for articulation with the turbinated bone; above this a second broad, shallow depression, which forms part of the **middle meatus**, surmounted above by a horizontal ridge less prominent than the inferior, the **superior turbinated crest** (*crista ethmoidalis*), for articulation with the middle turbinated process. Above the superior turbinated crest is a narrow, horizontal groove, which forms part of the **superior meatus**.

The **external or lateral surface** (*facies maxillaris*) is rough and irregular throughout the greater part of its extent, for articulation with the inner surface of the maxilla, its upper and back part being smooth where it enters into the formation of the sphenomaxillary fossa; it is also smooth in front, where it covers the orifice of the antrum. Toward the back part of this surface is a deep groove, the **pterygopalatine groove**, converted into a canal, the **posterior palatine canal**, by its articulation with the maxilla. It transmits the posterior or descending palatine vessels and the great or anterior palatine nerve from Meckel's ganglion.

Borders. — The **anterior border** (Fig. 79) is thin, irregular, and presents opposite the inferior turbinated crest a pointed, projecting lamina, the **maxillary process** (*processus maxillaris*), which is directed forward, and closes in the lower and back part of the opening of the antrum.

The **posterior border** (Fig. 80) presents a deep groove, the edges of which are serrated for articulation with the pterygoid process of the sphenoid. At the lower part of this border is seen a pyramidal process of bone, the **tuberosity of the palate** (*processus pyramidalis*), which is received into the angular interval between

FIG. 79.—Left palate bone. Internal view. (Enlarged.)

FIG. 80.—Left palate bone. Posterior view. (Enlarged.)

the two pterygoid plates of the sphenoid at their inferior extremity. This process presents at its back part a median groove and two lateral surfaces. The groove is smooth, and forms part of the pterygoid fossa, affording attachment to the Internal pterygoid muscle; while the lateral surfaces are rough and uneven, for articulation with the anterior border of each pterygoid plate. A few fibres of the Superior constrictor of the pharynx arise from the tuberosity of the palate bone. The base of this process, continuous with the horizontal portion of the bone, presents the apertures of the accessory descending palatine canals, through which pass the two smaller descending branches of Meckel's ganglion; while its outer surface is rough for articulation with the inner surface of the body of the maxilla.

The **superior border** of the vertical plate presents two well-marked processes separated by an intervening notch. The anterior, or larger, is called the orbital process; the posterior, the sphenoidal process.

Processes.—The **orbital process** (*processus orbitalis*), directed upward and outward, is placed on a higher level than the sphenoidal. It presents five surfaces,

which enclose a hollow cellular cavity, and is connected with the perpendicular plate by a narrow, constricted neck. Of these five surfaces, three are articular, two nonarticular or free surfaces. The three articular are the *anterior* or *maxillary surface*, which is directed forward, outward, and downward, is of an oblong form, and rough for articulation with the maxilla. The *posterior* or *sphenoidal surface* is directed backward, upward, and inward. It ordinarily presents a small, open cell, the *orbital sinus* (*sinus orbitalis*), which communicates with the sphenoidal cells, and the margins of which are serrated for articulation with the vertical part of the sphenoidal turbinated process. The *internal* or *ethmoidal surface* is directed inward, upward, and forward, and articulates with the lateral mass of the ethmoid bone. In some cases the cellular cavity opens on the internal surface of the bone; it then communicates with the posterior ethmoidal cells. More rarely it opens on both surfaces, and then communicates with both the posterior ethmoidal and the sphenoidal cells. The nonarticular or free surfaces are the *superior* or *orbital surface*, directed upward and outward, of triangular form, concave, smooth, and forming the back part of the floor of the orbit; and the *external* or *zygomatic surface*, directed outward, backward, and downward, of an oblong form, smooth, lying in the sphenomaxillary fossa, and looking into the zygomatic fossa. The latter surface is separated from the orbital by a smooth, rounded border, which enters into the formation of the sphenomaxillary fissure.

The **sphenoidal process** (*processus sphenoidalis*) of the palate bone is a thin, compressed plate, much smaller than the orbital, and directed upward and inward. It presents three surfaces and two borders. The *superior surface*, the smallest of the three, articulates with the under surface of the sphenoidal turbinated process; it presents a groove, which contributes to the formation of the pterygopalatine canal. The *internal surface* is concave, and forms part of the outer wall of the nasal fossa. The *external surface* is divided into an articular and a nonarticular portion; the former is rough, for articulation with the inner surface of the internal pterygoid plate of the sphenoid; the latter is smooth, and forms part of the sphenomaxillary fossa. The *anterior border* forms the posterior boundary of the sphenopalatine notch. The *posterior border*, serrated at the expense of the outer table, articulates with the inner surface of the internal pterygoid plate.

The orbital and sphenoidal processes are separated from each other by a deep notch, the **sphenopalatine notch** (*incisura sphenopalatina*), which is converted into a foramen, the **sphenopalatine foramen** (*foramen sphenopalatinum*), by articulation with the under surface of the body of the sphenoid bone. Sometimes the two processes are united above, and form between them a complete foramen (Figs. 79 and 80), or the notch is crossed by one or more spiculæ of bone, so as to form two or more foramina. In the articulated skull this foramen is seen to pass from the sphenomaxillary fossa into the back part of the superior meatus. It transmits the sphenopalatine vessels and the superior nasal and nasopalatine nerves.

Development.—From a *single* centre, which makes its appearance in membrane about the second month at the angle of junction of the two plates of the bone. From this point ossification spreads inward to the horizontal plate, downward into the tuberosity, and upward into the vertical plate. In the fetus the horizontal plate is much larger than the vertical, and even after it is fully ossified the whole bone is remarkable for its shortness.

Articulations.—With *six* bones—the sphenoid, ethmoid, maxilla, turbinated, vomer, and opposite palate.

Attachment of Muscles.—To *four*—the Tensor palati, Azygos uvulae, Internal pterygoid, and Superior constrictor of the pharynx.

The Turbinated Bone (Concha Nasalis Inferior).

The **turbinated bones** are situated one on each side of the outer wall of the nasal fossæ. Each consists of a layer of thin, spongy bone, curled upon itself like a scroll—hence its name “turbinated”—and extends horizontally along the outer wall of the nasal fossa, immediately below the orifice of the antrum (Fig. 81). Each bone presents two surfaces, two borders, and two extremities.

FIG. 81.—Nasal cavity, right lateral wall, from the left. (Spalteholz.)

Surfaces.—The **internal surface** (Fig. 82) is convex, perforated by numerous apertures, and traversed by longitudinal grooves and canals for the lodgement of arteries and veins. In the recent state it is covered by the lining membrane of the nose. The **external surface** is concave (Fig. 83), and forms part of the inferior meatus.

FIG. 82.—Right turbinated bone. Internal surface.

FIG. 83.—Right turbinated bone. External surface.

Borders.—Its **upper border** is thin, irregular, and connected to various bones along the outer wall of the nose. It may be divided into three portions; of these, the anterior articulates with the inferior turbinated crest of the maxilla; the posterior with the inferior turbinated crest of the palate bone; the middle portion of the

superior border presents three well-marked processes, which vary much in their size and form. Of these, the anterior and smallest is situated at the junction of the anterior fourth with the posterior three-fourths of the bone; it is small and pointed, and is called the **lacrimal process** (*processus lacrimalis*); it articulates by its apex with the anterior inferior angle of the lacrimal bone, and by its margins with the groove on the back of the nasal process of the maxilla, and thus assists in forming the canal for the nasal duct. At the junction of the two middle fourths of the bone, but encroaching on its posterior fourth, a broad, thin plate, the **ethmoidal process** (*processus ethmoidalis*), ascends to join the unciform process of the ethmoid; from the lower border of this process a thin lamina of bone curves downward and outward, hooking over the lower edge of the orifice of the antrum, which it narrows below; it is called the **maxillary process** (*processus maxillaris*), and fixes the bone firmly to the outer wall of the nasal fossa. The **inferior border** is free and thick, more especially in the middle of the bone. Both **extremities** are more or less narrow and pointed, the posterior being the more tapering. If the bone is held so that its outer concave surface is directed backward (*i. e.*, toward the holder), and its superior border, from which the lacrimal and ethmoidal processes project, upward, the lacrimal process will be directed to the side to which the bone belongs.¹

Development.—From a *single* centre, which makes its appearance about the middle of fetal life in the outer wall of the cartilaginous nasal septum.

Articulations.—With *four* bones—one of the cranium, the ethmoid, and three of the face, the maxilla, lacrimal, and palate.

No muscles are attached to this bone.

The Vomer.

The **vomer** is a single bone, situated vertically at the back part of the nasal fossæ, forming part of the septum of the nose (Fig 84). It is thin, somewhat like a ploughshare in form; but varies in different individuals, being frequently bent to one or the other side; it presents for examination two surfaces and four borders.

Surfaces.—The **lateral surfaces** are smooth, marked by small furrows for the lodgement of bloodvessels, and by a groove on each side, sometimes a canal, the **nasopalatine groove**, or **canal**, which runs obliquely downward and forward to the intermaxillary suture; it transmits the nasopalatine nerve.

Borders.—The **superior border**, the thickest, presents a deep groove, bounded on each side by a horizontal projecting leaf of bone; these leaves are the **alæ** (*alæ vomeris*). The groove formed by the alæ receives the rostrum of the sphenoid, while the alæ are overlapped and retained by the vaginal processes, which project on the under surface of the body of the sphenoid at the base of the pterygoid processes. At the front of the groove a fissure is left for the transmission of bloodvessels to the substance of the bone. The **inferior border**, the longest, is broad and uneven in front, where it articulates with the two maxillæ; thin and sharp behind, where it joins with the palate bones. The upper half of the **anterior border** usually consists of two laminæ of bone, in the groove between which is received the perpendicular plate of the ethmoid; the lower half, also separated into two lamellæ, receives between them the lower margin of the septal cartilage of the nose. The **posterior border** is free, concave, and separates the nasal fossæ behind. It is thick and bifid above, thin below.

The surfaces of the vomer are covered by mucous membrane, which is intimately connected with the periosteum, with the intervention of very little, if any, submucous connective tissue.

¹ If the lacrimal process is broken off, as is often the case, the side to which the bone belongs may be known by recollecting that the maxillary process is nearer the back than the front of the bone.

FIG. 84.—Vomer in situ.

Development.—The vomer at an early period consists of two laminæ, separated by a very considerable interval, and enclosing between them a plate of cartilage, the **vomerine cartilage**, which is prolonged forward to form the remainder of the septum. Ossification commences, about the eighth week, in the membrane at the postero-inferior part of this cartilage from two centres, one on each side of the middle line, which extend to form the two laminæ. The intervening cartilaginous plate is absorbed. They begin to coalesce at the lower part, but their union is not complete until after puberty.

Articulations.—With six bones—two of the cranium, the sphenoid and ethmoid, and four of the face, the maxillæ and the two palate bones; and with the cartilage of the septum.

The vomer has *no muscles* attached to it.

FIG. 85.—The vomer.

The Mandible, or Lower Jaw (Mandibula).

The **mandible**, the largest and strongest bone of the face, serves for the reception of the lower teeth. It consists of a curved, horizontal portion, the **body**, and two perpendicular portions, the **rami**, which join the back part of the body nearly at right angles.

The Body (*corpus mandibulae*) (Fig. 86).—The body is convex in its general outline, and curved somewhat like a horseshoe. It presents for examination two surfaces and two borders.

Surfaces.—The **external surface** is convex from side to side, concave from above downward. In the median line is a vertical ridge, the **symphysis**, which extends

from the upper to the lower border of the bone, and indicates the point of junction of the two pieces of which the bone is composed at an early period of life. The lower part of the ridge terminates in a prominent triangular eminence, the **mental process** (*protuberantia mentalis*). This eminence is rounded below, and often

FIG. 86.—The mandible. Outer surface. Side view.

presents a median depression separating two processes, the **mental tubercles** (*tubercula mentalia*). It forms the chin, a feature peculiar to the human skull. On either side of the symphysis, just below the cavities for the incisor teeth, is a depression, the **incisor fossa**, for the attachment of the Levator menti; more externally is

FIG. 87.—The mandible. Inner surface. Side view.

attached a portion of the Orbicularis oris, and still more externally, a foramen, the **mental foramen** (*foramen mentale*), for the passage of the mental vessels and nerve. This foramen is placed just below the interval between the two bicuspid teeth. Running outward from the base of the mental process on each side is a

ridge, the **external oblique line** (*linea obliqua*). The ridge is at first nearly horizontal, but afterward inclines upward and backward, and is continuous with the anterior border of the ramus; it affords attachment to the Depressor labii inferioris and Depressor anguli oris; below it the Platysma is attached.

The **internal surface** (Fig. 87) is concave from side to side, convex from above downward. In the middle line is an indistinct linear depression, corresponding to the symphysis externally; on either side of this depression, just below its centre, are two prominent tubercles, one above and one below, the **genial tubercles** (*spinae mentales*), which afford attachment, the upper pair to the Geniohyoglossi, the lower pair to the Geniohyoidei, muscles. Sometimes the tubercles on each side are blended into one; at others they all unite into an irregular eminence; or, again, nothing but an irregularity may be seen on the surface of the bone at this part. On either side of the genial tubercles is an oval depression, the **sublingual fossa** (*fovea sublingualis*), for the lodgement of the sublingual gland; and beneath the fossa a rough depression, the **digastric fossa** (*fossa digastrica*), on each side, which gives attachment to the anterior belly of the Digastric muscle.

At the back part of the sublingual fossa the **internal oblique line**, or **mylohyoid ridge** (*linea mylohyoidea*), commences; it is at first faintly marked, but becomes more distinct as it passes upward and outward, and is especially prominent opposite the last two molar teeth; it affords attachment throughout its whole extent to the Mylohyoid muscle; the Superior constrictor of the pharynx with the pterygomaxillary ligament being attached above its posterior extremity, near the alveolar margin. The portion of the bone above this ridge is smooth and covered by the mucous membrane of the mouth; the portion below presents an oblong depression, the **submaxillary fossa** (*fovea submaxillaris*), wider behind than in front, for the lodgement of the submaxillary gland. The external oblique line and the internal or mylohyoidean line divide the body of the bone into a superior or alveolar and an inferior or basilar portion.

Borders.—The **superior or alveolar portion** of the body (*pars alveolaris*) has above a narrow border which is wider and the margins of which are thicker behind than in front. It is hollowed into numerous cavities (*alveoli dentales*), for the reception of the teeth; these cavities are sixteen in number, and vary in depth and size according to the teeth which they contain. To the outer side of the alveolar border the Buccinator muscle is attached as far forward as the first molar tooth. The **inferior or basilar portion** (*basis mandibulae*) is rounded, longer than the superior and thicker in front than behind; it presents a shallow groove, just where the body joins the ramus, over which the facial artery turns.

The Perpendicular Portions or Rami (*rami mandibulae*).—The perpendicular portions or rami are of a quadrilateral form. Each presents for examination two surfaces, four borders, and two processes.

Surfaces.—The **external surface** is flat, marked with ridges, and gives attachment throughout nearly the whole of its extent to the Masseter muscle.

The **internal surface** presents about its centre an **oblique foramen** (*foramen mandibulare*), the beginning of the **inferior dental canal** (*canalis mandibulae*), which transmits the inferior dental vessels and nerve. The margin of this opening is irregular; it presents in front a prominent ridge, surmounted by a sharp spine, the **lingula** (*lingula mandibulae*), which gives attachment to the internal lateral ligament of the mandible, and at its lower and back part a notch leading to a groove, the **mylohyoidean groove** (*sulcus mylohyoideus*), which runs obliquely downward to the back part of the submaxillary fossa, and lodges the mylohyoid vessels and nerve. Behind the groove is a rough surface, for the insertion of the Internal pterygoid muscle. The **inferior dental canal** runs obliquely downward and forward in the substance of the ramus, and then horizontally forward in the body; it is here placed under the alveoli, with which it communicates by small openings.

On arriving at the incisor teeth, it turns back to communicate with the mental foramen, giving off two small canals, which run forward, to be lost in the cancellous tissue of the bone beneath the incisor teeth. This canal, in the posterior two-thirds of the bone, is situated nearer the internal surface of the jaw; and in the anterior third, nearer its external surface. Its walls are composed of compact tissue at either extremity, and of cancellous in the centre. It contains the inferior dental vessels and nerve, from which branches are distributed to the teeth through small apertures at the bases of the alveoli.

Borders.—The **lower border** of the ramus is thick, straight, and continuous with the body of the bone. At its junction with the posterior border is the **angle of the jaw** (*angulus mandibulae*). The angle is either inverted or everted, and marked by rough, oblique ridges on each side, for the attachment of the Masseter externally and the Internal pterygoid internally; the stylomaxillary ligament is attached to the angle between these muscles. The **anterior border** is thin above, thicker below, and continuous with the external oblique line. The **posterior border** is thick, smooth, rounded, and covered by the parotid gland. The **upper border** of the ramus is thin, and presents two processes, separated by a deep concavity, the **sigmoid notch** (*incisura mandibulae*). Of these processes, the anterior is the **coronoid**, the posterior the **condyloid**.

The **coronoid process** (*processus coronoideus*) is a thin, flat, triangular eminence, which varies in shape and size. Its anterior border is convex, and is continuous below with the anterior border of the ramus; its posterior border is concave, and forms the anterior boundary of the sigmoid notch. Its *external surface* is smooth, and affords attachment to the Temporal and Masseter muscles. Its *internal surface* gives insertion to the Temporal muscle, and presents a ridge which begins near the apex of the process and runs downward and forward to the inner side of the last molar tooth. Between this ridge and the anterior border is a grooved triangular area, the upper part of which gives attachment to the Temporal, the lower part to some fibres of the Buccinator.

The **condyloid process** (*processus condyloideus*), shorter but thicker than the coronoid, consists of two portions, the **condyle** (*capitulum mandibulae*), and the constricted portion which supports the condyle, the **neck** (*collum mandibulae*). The condyle is of an oblong form, its long axis being transverse, and set obliquely on the neck in such a manner that its outer end is a little more forward and a little higher than its inner. It is convex from before backward and from side to side, the articular surface extending farther on the posterior than on the anterior aspect. At its outer extremity is a small tubercle for the attachment of the external lateral ligament of the temporomandibular joint. The neck of the condyle is flattened from before backward, and strengthened by ridges which descend from the fore part and sides of the condyle. Its lateral margins are narrow, the external one giving attachment to part of the external lateral ligament. Its posterior surface is convex; its anterior is hollowed out on its inner side by a depression, the **pterygoid depression** (*fovea pterygoidea*), for the attachment of the External pterygoid muscle.

The **sigmoid notch** (*incisura mandibulae*), separating the two processes, is a deep semilunar depression, crossed by the masseteric vessels and nerve.

Development.—The mandible is ossified in the fibrous membrane covering the outer surfaces of Meckel's cartilages. These cartilages, one on either side, form the cartilaginous bar of the mandibular arch, being joined at the symphysis by mesodermal tissue. The proximal end of each cartilage is connected with the periotic capsule, and here serves to form the malleus and incus. The next succeeding portion as far as the lingula is replaced by fibrous tissue to form the sphenomandibular ligament. Between the lingula and the canine tooth the cartilage disappears, while the portion near the symphysis becomes ossified and incorporated with the incisor division of the mandible. This ossific centre appears in about the sixth week of fetal life—i. e., earlier than in any other bone except the clavicle; ossification is practically complete by the tenth

week. Accessory nuclei develop to form the condyle and the coronoid process, in the front part of both alveolar walls and along the front of the lower border of the bone.

These accessory nuclei possess no separate ossific centres, but ossification extends into them from the adjacent membrane bone and they undergo absorption. The inner alveolar border, usually described as arising from a separate ossific centre (*spenial centre*), is formed in the human mandible by an ingrowth from the main mass of the bone. At birth the bone consists of two halves, united by a fibrous symphysis, in which ossification takes place during the first year.

Articulation.—With the glenoid fossæ of the two temporal bones.

Attachment of Muscles.—To *fifteen pairs*—to its external surface, commencing at the symphysis, and proceeding backward: Levator menti, Depressor labii inferioris, Depressor anguli oris, Platysma, Buccinator, Masseter; a portion of the Orbicularis oris is also attached to this surface. To its internal surface, commencing at the same point: Geniohyoglossus, Geniohyoid, Mylohyoid, Digastric, Superior constrictor, Temporal, Internal pterygoid, External pterygoid.

FIG. 88.—Scheme showing ossification of the mandible, inner side (Low). The membrane bone is colored red. The greater part of Meckel's cartilage is colored blue. The upturned, stippled portion near the symphysis represents the part of Meckel's cartilage, which is surrounded and invaded by the membrane bone. The accessory nuclei of cartilage in the condyle, coronoid process, alveolar border, and body are indicated by stippled areas.

FIG. 89.—Scheme showing ossification of mandible from the outer side (Low). Membrane bone colored red. Accessory nuclei of cartilage stippled.

CHANGES PRODUCED IN THE MANDIBLE BY AGE.

The changes which the mandible undergoes after birth relate (1) to the alterations effected in the body of the bone by the first and second dentitions, the loss of the teeth in the aged, and the subsequent absorption of the alveoli; (2) to the size and situation of the dental canal; and (3) to the angle at which the ramus joins with the body.

At birth (Fig. 90) the bone consists of lateral halves, united by fibrous tissue. The body is a mere shell of bone, containing the sockets of the two incisor, the canine, and the two temporary molar teeth, imperfectly partitioned from one another. The dental canal is of large size, and runs near the lower border of the bone, the mental foramen opening beneath the socket of the first molar. The angle is obtuse (175 degrees), and the condyloid portion nearly in the same horizontal line with the body; the neck of the condyle is short, and bent backward. The coronoid process is of comparatively large size, and situated at right angles with the rest of the bone.

SIDE VIEW OF THE MANDIBLE AT DIFFERENT PERIODS OF LIFE.

After birth (Fig. 91) the two segments of the bone become joined at the symphysis, from below upward, in the first year; but a trace of separation may be visible in the beginning of the second year near the alveolar margin. The body becomes elongated in its whole length, but more especially behind the mental foramen, to provide space for the three additional teeth developed in this part. The depth of the body becomes greater, owing to increased growth of the alveolar part, to afford room for the fangs of the teeth, and by thickening of the subdental portion, which enables the jaw to withstand the powerful action of the masticatory muscles; but the alveolar portion is the deeper of the two, and, consequently, the chief part of the body lies above the oblique line. The dental canal after the second dentition is situated just above the level of the mylohyoid ridge, and the mental foramen occupies the position usual to it in the adult. The angle becomes less obtuse, owing to the separation of the jaws by the teeth. (About the fourth year it is 140 degrees.)

FIG. 90.—Mandible in newborn.

FIG. 91.—In child six to seven years of age.

FIG. 92.—In the adult.

FIG. 93.—In old age. (Spalteholz.)

In the adult (Fig. 92) the alveolar and basilar portions of the body are usually of equal depth. The mental foramen opens midway between the upper and lower border of the bone, and the dental canal runs nearly parallel with the mylohyoid line. The ramus is almost vertical in direction, and joins the body nearly at right angles.

In old age (Fig. 93) the bone becomes greatly reduced in size; for with the loss of the teeth the alveolar process is absorbed, and the basilar part of the bone alone remains, consequently, the chief part of the bone is *below* the oblique line. The dental canal, with the mental foramen opening from it, is close to the alveolar border. The rami are oblique in direction, the angle obtuse, and the neck of the condyle more or less bent backward.

The Sutures.

The bones of the cranium and face are connected to each other by means of **sutures**. That is, the articulating surfaces or edges of the bones are more or less **roughened** or uneven, and are closely adapted to each other, a small amount of intervening fibrous tissue, the **sutural ligament**, fastening them together. The cranial sutures may be divided into three sets: (1) Those at the vertex of the skull. (2) Those at the side of the skull. (3) Those at the base.

The sutures at the vertex of the skull are four—the **metopic**, the **sagittal**, the **coronal**, and the **lambdoid**.

The **metopic** or **frontal suture** (*sutura frontalis*) (Fig. 44) is usually noted in adults as a trivial fissure, just above the glabella. At birth the two halves of the frontal bone are separated by the suture. This suture is, as a rule, almost completely or completely closed during the fifth or sixth year, but occasionally it persists throughout life.

The **interparietal** or **sagittal suture** (*sutura sagittalis*) is formed by the junction of the two parietal bones, and extends from the middle of the frontal bone backward to the superior angle of the occipital. This suture is sometimes perforated, near its posterior extremity, by the parietal foramen; and in front, where it joins the coronal suture, a space is occasionally left which encloses a large Wormian bone.

The **frontoparietal** or **coronal suture** (*sutura coronalis*) (Fig. 99) extends transversely across the vertex of the skull, and connects the frontal with the parietal bones. It commences at the extremity of the greater wing of the sphenoid on one side, and terminates at the same point on the opposite side. The dentations of the suture are more marked at the sides than at the summit, and are so constructed that the frontal rests on the parietal above, while laterally the frontal supports the parietal.

The **occipitoparietal** or **lambdoid suture** (*sutura lambdoidea*) (Fig. 99), so called from its resemblance to the Greek letter Λ , connects the occipital with the parietal bones. It commences on each side at the mastoid portion of the temporal bone, and inclines upward to the end of the sagittal suture. The dentations of this suture are very deep and distinct, and are often interrupted by several small Wormian bones.

The **lateral sutures** (Fig. 99) extend from the external angular process of the frontal bone to the lower end of the lambdoid suture behind. The **anterior portion** is formed between the lateral part of the frontal bone above and the malar and greater wing of the sphenoid below, forming the **frontomalar suture** (*sutura zygomaticofrontalis*) and **frontosphenoidal suture** (*sutura sphenofrontalis*). These sutures can also be seen in the orbit, and form part of the so-called **transverse facial suture**. The **posterior portion** is formed between the parietal bone above and the greater wing of the sphenoid, the squamous and mastoid portions of the temporal bone below, forming the **sphenoparietal**, **squamoparietal**, and **mastoparietal** sutures.

The **sphenoparietal** (*sutura sphenoparietalis*) is very short; it is formed by the tip of the greater wing of the sphenoid, which overlaps the anterior inferior angle of the parietal bone.

The **squamoparietal** (*sutura squamosa*) is arched, and is formed by the squamous portion of the temporal bone overlapping the middle division of the lower border of the parietal.

The **mastoparietal** (*sutura parietomastoidea*), a short suture, deeply dentated, is formed by the posterior inferior angle of the parietal and the superior border of the mastoid portion of the temporal.

The sutures at the base of the skull (Fig. 98) are the basilar in the centre, and on each side the petro-occipital, the masto-occipital, the petrosphenoidal, and the squamosphenoidal.

The **basilar suture** (*fissura sphenoccipitalis*) is formed by the junction of the basilar surface of the occipital bone with the posterior surface of the body of the sphenoid. At an early period of life a thin plate of cartilage exists between these bones, but in the adult they become fused into one (*synchondrosis sphenoccipitalis*). Between the outer extremity of the basilar suture and the termination of the lambdoid an irregular suture exists, which is subdivided into two portions. The inner portion, formed by the union of the petrous part of the temporal with the occipital bone, is termed the **petro-occipital fissure** (*fissura petrooccipitalis*). The outer portion, formed by the junction of the mastoid part of the temporal with the occipital, is called the **masto-occipital suture** (*sutura occipitomastoidea*). Between the bones forming the petro-occipital suture a thin plate of cartilage exists; in the masto-occipital is occasionally found the opening of the mastoid foramen. Between the outer extremity of the basilar suture and the sphenoparietal an irregular suture may be seen, formed by the union of the sphenoid with the temporal bone. The inner and smaller portion of this suture is termed the **petrosphenoidal fissure** (*fissura sphenopetrosa*); it is formed between the petrous portion of the temporal and the greater wing of the sphenoid; the outer portion, of greater length and arched, is formed between the squamous portion of the temporal and the greater wing of the sphenoid; it is called the **squamosphenoidal suture** (*sutura sphenosquamosa*).

The cranial bones are connected with those of the face, and the facial bones with each other, by numerous sutures, which, though distinctly marked, have received no special names. The only remaining suture deserving especial consideration is the **transverse suture**. This extends across the upper part of the face, and is formed by the junction of the frontal with the facial bones; it extends from the external angular process of one side to the same point on the opposite side, and connects the frontal with the malar, the sphenoid, the ethmoid, the lacrimal, the maxillæ, and the nasal bones on each side (*sutura zygomaticofrontalis*; the orbital portion of the *sutura sphenofrontalis*, *sutura frontoethmoidalis*, *sutura frontolacrimalis*, *sutura frontomaxillaris*, *sutura nasofrontalis*).

The sutures remain separate for a considerable period after the complete formation of the skull. It is probable that they serve the purpose of permitting the growth of the bones at their margins, while their peculiar formation, together with the interposition of the sutural ligament between the bones forming them, prevents the dispersion of blows or jars received upon the skull. Humphry remarks, "that, as a general rule, the sutures are first obliterated at the parts in which the ossification of the skull was last completed—viz., in the neighborhood of the fontanelles; and the cranial bones seem in this respect to observe a similar law to that which regulates the union of the epiphyses to the shafts of the long bones." The same author remarks that the time of their disappearance is extremely variable; they are sometimes found well marked in skulls edentulous with age, while in others which have only just reached maturity they can hardly

be traced. The obliteration of the sutures takes place sooner on the inner than on the outer surface of the skull. The sagittal and coronal sutures are, as a rule, the first to become ossified—the process starting near the posterior extremity of the former and the lower ends of the latter.

THE SKULL AS A WHOLE.

The skull, formed by the union of the several cranial and facial bones already described, when considered as a whole is divisible into five regions—a superior region or **vertex**, an inferior region or **base**, two **lateral regions**, and an anterior region, the **face**.

The Vertex of the Skull.—The superior region, or **vertex**, presents two surfaces, an external and an internal.

Surfaces.—The **external surface** (*norma verticalis*) is bounded, in *front*, by the glabella and supraorbital ridges; *behind*, by the occipital protuberance and superior curved lines of the occipital bone; *laterally*, by an imaginary line extending from the outer end of the superior curved line, along the temporal ridge, to the external angular process of the frontal bone. This surface includes the greater part of the vertical portion of the frontal, the greater part of the parietal, and the superior third of the occipital bone; it is smooth, convex, of an elongated oval form, crossed transversely by the coronal suture, and from before backward by the sagittal, which terminates behind in the lambdoid. The point of junction of the coronal and sagittal sutures is named the **bregma**. The point of junction of the sagittal and lambdoid sutures is called the **lambda**, and is about $2\frac{3}{4}$ inches (7 cm.) above the external occipital protuberance. From before backward may be seen the frontal eminences and remains of the suture connecting the two lateral halves of the frontal bone; on each side of the sagittal suture are the parietal foramen and parietal eminence, and still more posteriorly the convex surface of the occipital bone. In the neighborhood of the parietal foramen the skull is often flattened, and the name of **obelion** is sometimes given to that point of the sagittal suture which lies exactly opposite to the parietal foramen.

The **internal or cerebral surface** is concave, presents depressions for the convolutions of the cerebrum, and numerous furrows for the lodgement of branches of the meningeal arteries. Along the middle line of this surface is a longitudinal groove, narrow in front, where it commences at the frontal crest, but broader behind, where it lodges the superior longitudinal sinus, and by its margin affords attachment to the falx cerebri. On either side of it are several depressions for the arachnoid villi, and at its back part the internal openings of the parietal foramina. This surface is crossed, in front, by the coronal suture; from before backward by the sagittal; behind, by the lambdoid.

The Base of the Skull (the Skull being without the Mandible).—The inferior region, or base of the skull, presents two surfaces—an internal or cerebral, and an external or basilar.

Surfaces.—The **internal or cerebral surface** (Fig. 94) presents three fossæ, called the anterior, middle, and posterior fossæ of the cranium.

The **anterior fossa** (*fossa cranii anterior*) (Fig. 94) is formed by the orbital plates of the frontal, the cribriform plate of the ethmoid, the anterior third of the superior surface of the body, and the upper surface of the lesser wings of the sphenoid bone, and is situated at a higher level than the other fossæ. It is the most elevated of the three fossæ, convex externally where it corresponds to the roof of the orbit, concave in the median line in the situation of the cribriform plate of the ethmoid. It is traversed on either side by three sutures, the ethmofrontal, ethmosphenoidal, and frontosphenoidal, and lodges the frontal lobes of the cerebrum. It presents,

posterior margin of which affords attachment to the falx cerebri; on either side of the crista galli, the **cribriform plate**, which supports the olfactory bulb, and presents three rows of foramina for the transmission of its nerve filaments, and in front a slit-like opening (*nasal slit*) for the nasal branch of the ophthalmic division of the trigeminal nerve. On the outer side of each olfactory groove are the internal openings of the anterior and posterior ethmoidal foramina, the former situated about the middle of the outer margin of the olfactory groove. The anterior ethmoidal foramen transmits the anterior ethmoidal vessels and the nasal nerve, which latter runs in a depression along the surface of the ethmoid to the slit-like opening above mentioned; while the posterior ethmoidal foramen opens at the back part of this margin under cover of the projecting lamina of the sphenoid, and transmits the posterior ethmoidal vessels. Farther back in the middle line is the **ethmoidal spine**, bounded behind by a slight elevation, separating two shallow longi-

FIG. 95.—Base of the skull. Interior view.

tudinal grooves which support the olfactory lobes. Behind this is a transverse sharp ridge, running outward on either side to the anterior margin of the optic foramen, and separating the anterior from the middle fossa of the base of the skull. The anterior fossa presents, laterally, depressions for the convolutions of the cerebrum and grooves for the lodgement of the anterior meningeal arteries.

The **middle fossa** (*fossa cranii media*) (Fig. 94), deeper than the preceding, is narrow in the middle line, but becomes wider at the side of the skull. It is bounded in *front* by the posterior margin of the lesser wings of the sphenoid, the anterior clinoid processes, and the ridge forming the anterior margin of the optic groove; *behind*, by the superior border of the petrous portions of the temporal and the dorsum sellæ; *externally*, by the squamous portions of the temporal and the anterior inferior angle of the parietal bones and greater wings of the sphenoid. On each side it is traversed by four sutures, the squamoparietal, sphenoparietal, squamo-

sphenoidal, and petrosphenoidal. In the middle line, from before backward, is the **optic groove**, which supports the optic commissure; the groove terminates on each side in the **optic foramen**, for the passage of the optic nerve and ophthalmic artery; behind the optic groove is the **olivary process** and laterally the **anterior clinoid processes**, to which are attached processes of the tentorium cerebelli. Farther back is the **sella turcica**, a deep depression which lodges the hypophysis, bounded in front by a small eminence on either side, the **middle clinoid process**, and behind by a broad, square plate of bone, the **dorsum sellae**, surmounted at each superior angle by a tubercle, the **posterior clinoid process**; beneath the latter process is a notch, for the abducent nerve. On each side of the sella turcica is the **carotid groove**; it is broad, shallow, and curved somewhat like the italic letter *f*; it commences behind at the foramen lacerum medium, and terminates on the inner

FIG. 96.—Median sagittal section of the skull.

side of the anterior clinoid process, and presents along its outer margin a ridge of bone. This groove lodges the cavernous sinus, the internal carotid artery, and the nerves which enter the orbit. The sides of the middle fossa are of considerable depth; they present depressions for the convolutions of the cerebrum and grooves for the branches of the middle meningeal artery; the latter commence on the outer side of the foramen spinosum, and consist of two large branches, an anterior and a posterior; the former passing upward and forward to the anterior inferior angle of the parietal bone, the latter passing upward and backward. The following foramina may also be seen on either side from before backward. Most anteriorly is seen the **sphenoidal fissure** (*foramen lacerum anterius*), formed above by the lesser wing of the sphenoid; below, by the greater wing; internally, by the body of the sphenoid; and sometimes completed externally by the orbital plate of the frontal bone. It

transmits the third, the fourth, the three branches of the ophthalmic division of the trigeminal, the abducent nerve, some filaments from the cavernous plexus of the sympathetics, the orbital branch of the middle meningeal artery, a recurrent branch from the lacrimal artery to the dura, and the ophthalmic vein. Behind the inner extremity of the sphenoidal fissure is the **foramen rotundum**, for the passage of the second division of the trigeminal nerve; still more posteriorly is seen a small orifice, the **foramen Vesalii**, an opening situated between the foramen rotundum and the foramen ovale, a little internal to both; it varies in size in different individuals, and is often absent; when present it transmits a small vein and opens below into the outer side of the scaphoid fossa. Behind and external to the latter opening is the **foramen ovale**, which transmits the third division of the trigeminal nerve, the small meningeal artery, and sometimes the small petrosal nerve. On the outer side of the foramen ovale is the **foramen spinosum**, for the passage of the middle meningeal artery; occasionally a small foramen (*canaliculus innominatus*) for the transmission of the small superficial petrosal nerve is seen internal to the foramen spinosum. On the inner side of the foramen ovale is the **foramen lacerum medium**; the lower part of this aperture is filled in the recent state with cartilage which is pierced by the Vidian nerve and a meningeal branch from the ascending pharyngeal artery. On the anterior surface of the petrous portion of the temporal bone is seen, from without inward, the eminence caused by the projection of the superior semicircular canal; in front of and a little outside this is a depression corresponding to the roof of the tympanum; the groove leading to the hiatus Fallopii, for the transmission of the petrosal branch of the Vidian nerve and the petrosal branch of the middle meningeal artery; beneath it, a smaller groove, for the passage of the lesser petrosal nerve; and, near the apex of the bone, the depression for the Gasserian ganglion; and the internal orifice of the carotid canal, for the passage of the internal carotid artery and carotid plexus of nerves.

The **posterior fossa** (*fossa cranii posterior*), deeply concave, is the largest of the three, and situated on a lower level than either of the preceding. It is formed by the posterior third of the superior surface of the body of the sphenoid, by the occipital, the petrous and mastoid portions of the temporal, and the posterior inferior angle of the parietal bones; it is crossed on either side by four sutures, the petro-occipital, the masto-occipital, the mastoparietal, and the basilar; and lodges the cerebellum, pons, and medulla oblongata. It is separated from the middle fossa in the median line by the dorsum sellæ, and on each side by the superior border of the petrous portion of the temporal bone. This border serves for the attachment of the tentorium cerebelli, is grooved for the superior petrosal sinus, and at its inner extremity presents a notch, in which rests the trigeminal nerve. The circumference of the fossa is bounded posteriorly by the grooves for the lateral (transverse) sinuses. In the centre of this fossa is the **foramen magnum**, bounded on either side by a rough tubercle, which gives attachment to the odontoid or check ligaments; and a little above these are seen the internal openings of the **anterior condylar foramina**, through which pass the hypoglossal nerves and meningeal branches from the ascending pharyngeal arteries. In front of the foramen magnum is a grooved surface, formed by the basilar process of the occipital bone and by the posterior third of the superior surface of the body of the sphenoid, which supports the medulla oblongata and pons; and articulates on each side with the petrous portion of the temporal bone, forming the **petro-occipital suture**, the anterior half of which is grooved for the inferior petrosal sinus, the posterior half being encroached upon by the **foramen lacerum posterius** (*foramen jugulare*). This foramen presents three compartments—through the anterior passes the inferior petrosal sinus; through the posterior, the lateral sinus and some meningeal branches from the occipital and ascending pharyngeal arteries; and through the middle, the glossopharyngeal, vagus, and spinal accessory nerves. Above the jugular foramen

is the **internal auditory meatus**, for the facial and auditory nerves and auditory artery; behind and external to this is the slit-like opening leading into the **aqueductus vestibuli**, which lodges the ductus endolymphaticus; while between the two latter, and near the superior border of the petrous portion, is a small, triangular depression, the remains of the **floccular fossa**, which lodges a process of the dura and occasionally transmits a small vein from the substance of the bone. Behind the foramen magnum are the quadrilateral **inferior occipital fossæ**, which lodge the hemispheres of the cerebellum, separated from each other by the **internal occipital crest**, which serves for the attachment of the falx cerebelli and lodges the occipital sinus. The posterior fossæ are limited above by the deep transverse grooves for the lodgement of the lateral sinuses, which diverge forward on each side from a depression in the mesal plane, the **torcular**. These channels, in their passage outward, groove the occipital bone, the posterior inferior angles of the parietals, the mastoid portions of the temporals, and the jugular processes of the occipital, and terminate at the back part of the jugular foramen. Where the lateral sinus grooves the mastoid portion of the temporal bone the orifice of the **mastoid foramen** may be seen. Just previous to the termination of the groove the **posterior condylar foramen** opens into it. Neither foramen is constant.

The **basilar surface** (*norma basalis*) (Fig. 97) of the skull is extremely irregular. It is bounded in front by the incisor teeth in the maxillæ; behind by the superior curved lines of the occipital bone; and laterally by the alveolar arch, the lower border of the malar bones, the zygoma, and an imaginary line extending from the zygoma to the mastoid process and extremity of the superior curved line of the occiput. It is formed by the palatal processes of the maxillæ and palate bones, the vomer, the pterygoid processes, under surface of the greater wings, spinous processes and part of the body of the sphenoid, the under surface of the squamous, mastoid, and petrous portions of the temporals, and the under surface of the occipital bone. The anterior part of the base of the skull is raised above the level of the rest of this surface (when the skull is turned over for the purpose of examination), is surrounded by the alveolar process, which is thicker behind than in front, and excavated by sixteen depressions for the lodgement of the teeth of the maxillæ, the cavities varying in depth and size according to the teeth they contain. Immediately behind the incisor teeth is the **anterior palatine fossa**. At the bottom of this fossa may usually be seen four apertures, two placed laterally, the **foramina of Stenson**, which open above, one in the floor of each nostril, and transmit the anterior branch of the posterior palatine vessels, and two in the median line in the intermaxillary suture, the **foramina of Scarpa**, one in front of the other, the anterior transmitting the left, and the posterior (the larger) the right, nasopalatine nerve. These two lateral canals are sometimes wanting, or they may join to form a single one, or one of them may open into one of the lateral canals above referred to. The palatine vault is concave, uneven, perforated by numerous foramina, marked by depressions for the palatine glands, and crossed by a crucial suture, formed by the junction of the four bones of which it is composed. At the front part of this surface a delicate linear suture may frequently be seen, passing outward and forward from the anterior palatine fossa to the interval between the lateral incisor and canine teeth, and marking off the **premaxillary portion** of the bone. At each posterior angle of the hard palate is the **posterior palatine foramen**, for the transmission of the posterior palatine vessels and great descending palatine nerve; and running forward and inward from it a groove, for the same vessels and nerve. Behind the posterior palatine foramen is the **tuberosity of the palate bone**, perforated by one or more **accessory posterior palatine canals**, and marked by the commencement of a ridge which runs transversely inward, and serves for the attachment of the tendinous expansion of the Tensor palati muscle. Projecting backward from the centre of the posterior border of the hard palate is the **posterior**

nasal spine, for the attachment of the Azygos uvulae muscle. Behind and above the hard palate is the posterior aperture of the nares, divided into two parts by the

FIG. 97.—Base of the skull. External surface.

vomer, bounded above by the body of the sphenoid, below by the horizontal plate of the palate bone, and laterally by the internal pterygoid plate of the sphenoid. Each aperture measures about an inch in the vertical and about half an inch in the transverse direction. At the base of the vomer may be seen the expanded alæ of this bone, receiving between them, on each side, the **rostrum of the sphenoid**. Near the lateral margins of the vomer, at the root of the pterygoid processes, are the **pterygopalatine canals**. The pterygoid process, which bounds the posterior nares on each side, presents near its base the **pterygoid** or **Vidian canal**, for the Vidian nerve and artery. Each process consists of two plates, which bifurcate at the extremity to receive the tuberosity of the palate bone, and are separated behind by the pterygoid fossa, which lodges the Internal pterygoid muscle. The internal

FIG. 98.—Base of the skull. External surface.

plate is long and narrow, presenting on the border of its base the **scaphoid fossa**, for the origin of the Tensor palati muscle, and at its extremity the **hamular process**, around which the tendon of this muscle turns. The external pterygoid plate is broad, forms the inner boundary of the **zygomatic fossa**, and affords attachment by its outer surface to the External pterygoid muscle.

Behind the nasal fossæ in the middle line is the basilar surface of the occipital bone, presenting in its centre the **pharyngeal spine**, for the attachment of the Superior constrictor muscle of the pharynx, with depressions on each side for the insertion of the Rectus capitis anticus major and minor. At the base of the external pterygoid plate is the **foramen ovale**, for the transmission of the third division of the trigeminal nerve, the small meningeal artery, and sometimes the small petrosal nerve; behind this, the **foramen spinosum**, which transmits the middle

meningeal artery, and the prominent spinous process of the sphenoid, which gives attachment to the internal lateral ligament of the mandible and the Tensor palati muscle. External to the spinous process is the **glenoid fossa**, divided into two parts by the Glaserian fissure (page 88), the anterior portion concave, smooth, bounded in front by the **eminentia articularis**, and serving for the articulation of the condyle of the mandible; the posterior portion rough, bounded behind by the **tympanic plate**, and serving for the reception of part of the parotid gland. Emerging from between the laminae of the vaginal process of the tympanic plate is the **styloid process**, and at the base of this process is the **stylomastoid foramen**, for the exit of the facial nerve and entrance of the stylomastoid artery. External to the stylomastoid foramen is the **auricular fissure**, for the exit of the auricular branch of the vagus, bounded behind by the mastoid process. Upon the inner side of the mastoid process is a deep groove, the **digastric fossa**; and a little more internally the **occipital groove**, for the occipital artery. At the base of the internal pterygoid plate is a large and somewhat triangular aperture, the **foramen lacerum medium**, bounded in *front* by the greater wing of the sphenoid, *behind* by the apex of the petrous portion of the temporal bone, and *internally* by the body of the sphenoid and basilar process of the occipital bone; it presents in front the posterior orifice of the Vidian canal; behind, the aperture of the carotid canal. The basilar surface of this opening is filled in the recent state by fibrocartilaginous substance; across its upper or cerebral aspect passes the internal carotid artery. External to this aperture the **petrosphenoidal suture** is observed, at the outer termination of which is seen the orifice of the canal for the Eustachian tube and that for the Tensor tympani muscle. Behind this suture is seen the under surface of the petrous portion of the temporal bone, presenting, from within outward, the quadrilateral, rough surface, part of which affords attachment to the Levator palati and Tensor tympani muscles; posterior to this surface is the orifice of the **carotid canal** and the orifice of the **aqueductus cochleae**, the former transmitting the internal carotid artery and the ascending branches of the superior cervical ganglion of the sympathetic, the latter serving for the passage of a small artery to and a small vein from the cochlea. Behind the carotid canal is a large aperture, the **jugular foramen**, formed in *front* by the petrous portion of the temporal, and *behind* by the occipital; it is generally larger on the right than on the left side, and is divided into three compartments by processes of dura. The anterior is for the passage of the inferior petrosal sinus; the posterior, for the lateral sinus and some meningeal branches from the occipital and ascending pharyngeal arteries; the central one, for the glossopharyngeal, vagus, and spinal accessory nerves. On the ridge of the bone dividing the carotid canal from the jugular foramen is the small foramen for the transmission of Jacobson's nerve (tympanic branch of the glossopharyngeal); and on the wall of the jugular foramen, near the root of the styloid process, is the small aperture for the transmission of the auricular branch of the vagus nerve (Arnold's nerve). Behind the basilar surface of the occipital bone is the **foramen magnum**, bounded on each side by the condyles, rough internally for the attachment of the check or odontoid ligaments, and presenting externally a rough surface, the **jugular process**, which serves for the attachment of the Rectus capitis lateralis muscle and the lateral occipitoatlantal ligament. The middle of the anterior margin of the foramen magnum is called the **basion**. The mid-point of the posterior margin is called the **opisthion**. On either side of each condyle anteriorly is the **anterior condyloid fossa**, continued as the **anterior condylar foramen**, for the passage of the hypoglossal nerve and often a meningeal branch of the ascending pharyngeal artery. Behind each condyle is the **posterior condyloid fossa**, continued as the **posterior condylar foramen**, for the transmission of a vein to the lateral sinus. Behind the foramen magnum is the **external occipital crest**, terminating above at the **external occipital protuberance**, while on each side are seen the **superior and inferior curved lines**;

these, as well as the surfaces of bone between them, are rough for the attachment of the muscles, which are enumerated on page 70.

The Lateral Region of the Skull.—The *norma lateralis* is of a somewhat triangular form, the base of the triangle being formed by a line extending from the external angular process of the frontal bone along the temporal ridge backward to the outer extremity of the superior curved line of the occiput; and the sides by two lines, the one drawn downward and backward from the external angular process of the frontal bone to the angle of the mandible, the other from the angle of the mandible upward and backward to the outer extremity of the superior curved line. This region is divisible into three portions—temporal fossa, mastoid portion, and zygomatic or infratemporal fossa.

FIG. 99.—Lateral aspect of the skull.

The Temporal Fossa (*fossa temporalis*).—The temporal fossa is bounded above and behind by the temporal ridges, which extend from the external angular process of the frontal upward and backward across the frontal and parietal bones, curving downward behind to terminate in the posterior root of the zygomatic process. In *front* it is bounded by the frontal, malar, and greater wing of the sphenoid; *externally* by the zygomatic arch formed conjointly by the malar and temporal bones; *below*, it is separated from the zygomatic fossa by the **pterygoid ridge**, seen on the outer surface of the greater wing of the sphenoid. This fossa is formed by five bones, part of the frontal, greater wing of the sphenoid, parietal, squamous portion of the temporal and malar bones, and is traversed by six sutures, part of the frontomalar, sphenomalar, coronal, sphenoparietal, squamoparietal, and squamosphenoidal. The point where the coronal suture crosses the superior temporal ridge is named the **stephanion**; and the region where the four bones, the parietal, the frontal, the squamous, and the greater wing of the sphenoid, meet, at the anterior inferior

angle of the parietal bone, is named the **pterion**. This point is about on a level with the external angular process of the frontal bone and about one and a half inches (3.75 cm.) behind it. This fossa is deeply concave in front, convex behind, traversed by grooves which lodge branches of the deep temporal arteries, and filled by the Temporal muscle.

The Mastoid Portion.—The mastoid portion of the side of the skull is bounded in front by the anterior root of the zygoma; above, by a line which runs from the posterior root of the zygoma to the end of the mastoparietal suture; behind and below by the masto-occipital suture. It is formed by the mastoid and part of the squamous and petrous portions of the temporal bone; its surface is convex and rough for the attachment of muscles, and presents, from behind forward, the **mastoid foramen**, the **mastoid process**, the **external auditory meatus** surrounded by the **tympanic plate**, and, most anteriorly, the **temporomaxillary articulation**. The point where the posterior inferior angle of the parietal meets the occipital and mastoid portion of the temporal is named the **asterion**.

FIG. 100.—Left zygomatic fossa.

The Zygomatic Fossa (*fossa infratemporalis*).—The zygomatic fossa is an irregularly shaped cavity, situated below and on the inner side of the zygoma; bounded in *front* by the zygomatic surface of the maxilla and the ridge which descends from its malar process; *behind*, by the posterior border of the external pterygoid plate and the eminentia articularis; *above*, by the pterygoid ridge on the outer surface of the greater wing of the sphenoid and the under part of the squamous portion of the temporal; *below*, by the alveolar border of the maxilla; *internally*, by the external pterygoid plate; and *externally*, by the zygomatic arch and ramus of the mandible (Fig. 100). It contains the lower part of the Temporal, the External and Internal pterygoid muscles, the internal maxillary artery and vein, and inferior maxillary

nerve and their branches. In its roof are seen the foramen ovale and the foramen spinosum; on its anterior wall open the posterior dental canals. At its upper and inner part may be observed the **sphenomaxillary** and **pterygomaxillary fissures**.

The **sphenomaxillary fissure** (*fissura orbitalis inferior*), horizontal in direction, opens into the outer and back part of the orbit. It is formed *above* by the lower border of the orbital surface of the greater wing of the sphenoid; *below*, by the external border of the orbital surface of the maxilla and a small part of the palate bone; *externally*, by a small part of the malar bone; *internally*, it joins at right angles with the pterygomaxillary fissure. This fissure permits the orbit to communicate with three fossæ—the **temporal**, **zygomatic**, and **sphenomaxillary fossæ**; it transmits the superior maxillary nerve and its orbital branch, the infraorbital vessels, and ascending branches from the sphenopalatine or Meckel's ganglion.

The **pterygomaxillary fissure** is vertical, and descends at right angles from the inner extremity of the preceding; it is a V-shaped interval formed by the divergence of the maxilla from the pterygoid process of the sphenoid. It serves to connect the sphenomaxillary fossa with the zygomatic fossa, and transmits the internal maxillary artery.

The Sphenomaxillary Fossa (*fossa pterygopalatina*).—The sphenomaxillary fossa is a small, triangular space situated at the angle of junction of the sphenomaxillary and pterygomaxillary fissures, and placed beneath the apex of the orbit. It is formed *above* by the under surface of the body of the sphenoid and by the orbital process of the palate bone; in *front*, by the maxilla; *behind*, by the anterior surface of the base of the pterygoid process and lower part of the anterior surface of the greater wing of the sphenoid; *internally*, by the vertical plate of the palate. This fossa has three fissures terminating in it—the **sphenoidal**, **sphenomaxillary**, and **pterygomaxillary**; it communicates with the orbit by the sphenomaxillary fissure; with the nasal fossæ by the sphenopalatine foramen, and with the zygomatic fossa by the pterygomaxillary fissure. It also communicates with the cavity of the cranium, and has opening into it five foramina. Of these, there are three on the posterior wall—the **foramen rotundum** above; below and internal to this, the **Vidian canal**; and still more inferiorly and internally, the **pterygopalatine canal**. On the inner wall is the **sphenopalatine foramen**, by which the sphenomaxillary communicates with the nasal fossa; and below is the superior orifice of the **posterior palatine canal**, besides occasionally the orifices of the accessory posterior palatine canals. The fossa contains the superior maxillary nerve and Meckel's ganglion, and the termination of the internal maxillary artery.

The Anterior Region of the Skull (*norma frontalis*).—The **norma frontalis** forms the face, is of an oval form, presents an irregular surface, and is excavated for the reception of two of the organs of sense, the eyes and the nose. It is bounded *above* by the glabella and margins of the orbit; *below*, by the prominence of the chin; on *each side* by the malar bone and interior margin of the ramus of the mandible. In the median line are seen from above downward the **glabella**, and diverging from it are the **superciliary ridges**, which indicate the situation of the frontal sinuses and support the eyebrow. Beneath the glabella is the frontonasal suture, the mid-point of which is termed the **nasion**, and below this is the arch of the nose, formed by the nasal bones, and the nasal processes of the maxillæ. The nasal arch is convex from side to side, concave from above downward, presenting in the median line the **internasal suture** (*sutura internasalis*), formed between the nasal bones, laterally, on either side, the **nasomaxillary suture** (*sutura nasomaxillaris*), formed between the nasal bone and the nasal process of the maxilla. Below the nose is seen the opening of the **apertura pyriformis**, which is heart-shaped, with the narrow end upward, and presents laterally the thin, sharp margins serving

¹ Occasionally the maxilla and the sphenoid articulate with each other at the anterior extremity of this fissure; the malar is then excluded from entering into its formation.

for the attachment of the lateral cartilages of the nose, and in the middle line below a prominent process, the **anterior nasal spine**, bounded by two deep notches. Below this is the **intermaxillary suture** (*sutura intermaxillaris*), and on each side of it the **incisive fossa**. Beneath this fossa are the alveolar processes of the maxilla and mandible, containing the incisor teeth, and at the lower part of the median line the symphysis of the chin, the **mental process**, with its two mental tubercles, separated by a median groove, and the **incisive fossa** of the mandible.

On each side, proceeding from above downward, is the **supraorbital ridge**, terminating externally in the **external angular process** at its junction with the malar, and internally in the **internal angular process**; toward the inner third of this ridge is the **supraorbital notch** or **foramen**, for the passage of the supraorbital vessels

FIG. 101.—Anterior aspect of the skull.

and nerve. Beneath the supraorbital ridge is the opening of the **orbit**, bounded externally by the orbital ridge of the malar bone; below, by the orbital ridge formed by the malar and maxilla; internally, by the nasal process of the maxilla and the **internal angular process** of the frontal bone. On the outer side of the orbit is the quadrilateral outer surface of the malar bone, perforated by one or two small **malar foramina**. Below the inferior margin of the orbit is the **infra-orbital foramen**, the termination of the **infraorbital canal**, and beneath this the **canine fossa**, which gives attachment to the Levator anguli oris; still lower are the **alveolar processes**, containing the teeth of the upper and lower jaws. Beneath the alveolar arch of the mandible is the **mental foramen**, for the passage of the mental

vessels and nerve, the **external oblique line**, and at the lower border of the bone, at the point of junction of the body with the ramus, a shallow groove for the passage of the facial artery.

The Orbits.—The orbits (Fig. 102) are two quadrilateral pyramidal cavities, situated at the upper and anterior part of the face, their bases being directed forward and outward, and their apices backward and inward, so that the axes of the two, if continued backward, would meet over the body of the sphenoid bone. Each orbit (*orbita*) is formed of *seven* bones—the frontal, sphenoid, ethmoid, maxilla, malar, lacrimal, and palate; but three of these, the frontal, ethmoid, and sphenoid, enter into the formation of *both* orbits, so that the two cavities are formed of *eleven* bones only. Each cavity presents for examination a **roof**, a **floor**, an **inner** and an **outer wall**, four **angles**, a **base**, and an **apex**.

FIG. 102.—Anterolateral region of the skull.

The **roof** (*paries superior*) is concave, directed downward and slightly forward, and formed in *front* by the orbital plate of the frontal; *behind*, by the lesser wing of the sphenoid. This surface presents internally the depression for the cartilaginous pulley of the Superior oblique muscle; externally, the depression for the lacrimal gland; and posteriorly, the suture connecting the frontal and lesser wing of the sphenoid.

The **floor** (*paries inferior*) is directed upward and outward, and is of less extent

than the roof; it is formed chiefly by the orbital surface of the maxilla; in *front*, to a small extent, by the orbital process of the malar, and *behind*, by the superior surface of the orbital process of the palate. This surface presents at its anterior and internal part, just external to the lacrimal groove, a depression for the attachment of the Inferior oblique muscle; externally, the suture between the malar and the maxilla; near its middle, the **infraorbital groove**; and posteriorly, the suture between the maxilla and palate bone.

The **inner** or **medial wall** (*paries medialis*) is flattened, nearly vertical, and formed from before backward by the nasal process of the maxilla, the lacrimal, os planum of the ethmoid, and a small part of the body of the sphenoid. This surface presents the **lacrimal groove** and **crests of the lacrimal bone**, and the sutures connecting the lacrimal with the maxilla, the ethmoid with the lacrimal in front, and the ethmoid with the sphenoid behind.

The **outer** or **lateral wall** (*paries lateralis*) is directed forward and inward, and is formed in *front* by the orbital process of the malar bone; *behind*, by the orbital surface of the greater wing of the sphenoid. On it are seen the orifices of one or two malar canals, and the suture connecting the sphenoid and malar bones.

Of the **angles**, the **superior external** is formed by the junction of the upper and outer walls; it presents from before backward, the suture connecting the frontal with the malar in front and with the greater wing of the sphenoid behind; quite posteriorly is the foramen lacerum anterius, or sphenoidal fissure, which transmits the third, the fourth, the three branches of the ophthalmic division of the trigeminal, the abducent nerve, some filaments from the cavernous plexus of the sympathetics, the orbital branch of the middle meningeal artery, a recurrent branch from the lacrimal artery to the dura, and the ophthalmic vein. The **superior internal** is formed by the junction of the upper and inner wall, and presents the suture connecting the frontal bone with the lacrimal in front and with the ethmoid behind. The point of junction of the anterior border of the lacrimal with the frontal has been named the **dacryon**. This angle presents two foramina, the **anterior** and **posterior ethmoidal foramina**, the former transmitting the anterior ethmoidal vessels and nasal nerve, the latter the posterior ethmoidal vessels. The **inferior external**, formed by the junction of the outer wall and floor, presents the **sphenomaxillary fissure**, which transmits the superior maxillary nerve and its orbital branches, the infraorbital vessels, and the ascending branches from the sphenopalatine or Meckel's ganglion. The **inferior internal** is formed by the union of the lacrimal bone and the os planum of the ethmoid with the maxilla and palate bone.

The **circumference** or **base** of the orbit, quadrilateral in form, is bounded *above* (*margo supraorbitalis*) by the supraorbital ridge; *below* (*margo infraorbitalis*), by the anterior border of the orbital plate of the malar and maxilla; *externally*, by the external angular process of the frontal and malar bones; *internally*, by the internal angular process of the frontal and the nasal process of the maxilla. The circumference is marked by three sutures, the frontomaxillary internally, the frontomalar externally, and the malomaxillary below; it contributes to the formation of the lacrimal groove, and presents, above, the supraorbital notch (or foramen), for the passage of the supraorbital vessels and nerve.

The **apex** is situated at the back of the orbit and corresponds to the **optic foramen**,¹ a short circular canal which transmits the optic nerve and ophthalmic artery. It will thus be seen that there are *nine* openings communicating with each orbit—viz., the optic foramen, sphenoidal fissure, sphenomaxillary fissure, supraorbital foramen, infraorbital canal, anterior and posterior ethmoidal foramina, malar foramina, and the canal for the nasal duct.

¹ Quain, Testut, and others give the apex of the orbit as corresponding with the inner end of the sphenoidal fissure. It seems better, however, to adopt the statement in the text, since the muscles of the eyeball take origin around the optic foramen, and diverge from it to the globe of the eye.

The Nasal Cavity.—The nasal cavities (*cavum nasi*), or **nasal fossæ** (Figs. 81 and 103), are two large, irregular cavities situated on either side of the middle line of the face, extending from the base of the cranium to the roof of the mouth, and separated from each other by a thin vertical septum, the **septum of the nose** (*septum nasi osseum*), formed by the perpendicular plate of the ethmoid and by the vomer. Each cavity communicates by a large aperture, the **anterior nasal aperture** (*apertura pyriformis*),¹ with the front of the face, and by the two **posterior nares** (*choanæ*) with the nasopharynx behind. These fossæ are much narrower above than below, and in the middle than at the anterior or posterior openings; their depth, which is considerable, is much greater in the middle than at either extremity. The nasal fossæ are surrounded by four other fossæ—above is the **cranial fossa**;

FIG. 103.—Nasal cavity, right lateral wall, from the left. (Spalteholz.)

laterally, the **orbital fossæ**; and below, the **cavity of the mouth**. Each nasal fossa communicates with four sinuses—the frontal above, the sphenoidal behind, and the maxillary and ethmoidal on the outer wall. Each fossa also communicates with four cavities—with the orbit by the **lacrimal groove**, with the mouth by the **anterior palatine canal**, with the cranium by the **olfactory foramina**, and with the sphenomaxillary fossa by the **sphenopalatine foramen**; and they occasionally communicate with each other by an aperture in the septum. The bones entering into their formation are *fourteen* in number—three of the cranium, the frontal-sphenoid, and ethmoid, and all the bones of the face, excepting the malar and mandible. Each cavity is bounded by a roof, a floor, an inner and an outer wall.

The **upper wall**, or **roof** (Fig. 104), is long, narrow, and horizontal in its centre, but slopes downward at its anterior and posterior extremities; it is formed in *front* by the nasal bones and nasal spine of the frontal, which are directed downward and forward; in the *middle*, by the cribriform plate of the ethmoid, which is hori-

¹ In the skull freed of soft parts the anterior nasal cavities open in front by the apertura pyriformis. In the skull with the soft parts in place they open by the anterior nares.

zontal; and *behind*, by the under surface of the body of the sphenoid and sphenoidal turbinated process, the ala of the vomer and the sphenoidal process of the palate bone, which are directed downward and backward. This surface presents, from before backward, the internal aspect of the nasal bones; on their outer side, the suture formed between the nasal bone and the nasal process of the maxilla; on their inner side, the elevated crest which receives the nasal spine of the frontal and the perpendicular plate of the ethmoid, and articulates with its fellow of the opposite side; while the surface of the bones is perforated by a few small vascular apertures, and presents the longitudinal groove for the nasal nerve; farther back is the **transverse suture**, connecting the frontal with the nasal in front, and the ethmoid behind, the **olfactory foramina** and **nasal slit** on the under surface of the cribriform plate, and the suture between it and the sphenoid behind; quite posteriorly are seen the **sphenoidal turbinated process**, the orifice of the **sphenoidal sinus**, and the articulation of the **ala of the vomer** with the under surface of the body of the sphenoid.

FIG. 104.—Coronal section of the face, passing through the third molar tooth. (Poirier and Charpy.)

The **floor** (Figs. 103 and 104) is flattened from before backward, concave from side to side, and wider in the middle than at either extremity. It is formed in *front* by the palatal process of the maxilla; *behind*, by the palatal process of the palate bone. This surface presents, from before backward, the **anterior nasal spine**; behind this, the upper orifices of the **anterior palatine canal**; the elevated crest which articulates with the vomer; and behind, the suture between the palate and maxilla, and the **posterior nasal spine**.

The **inner or medial wall, or septum** (Figs. 104 and 106), is a thin vertical partition which separates the nasal fossæ from each other. It is formed, in *front*, by the crest of the nasal bones and nasal spine of the frontal; in the *middle*, by the perpendicular plate of the ethmoid; *behind*, by the vomer and rostrum of the sphenoid; *below*, by the crests of the maxillæ and palate bones. It presents, in *front*, a large, triangular notch, which receives the septal cartilage of the nose; and *behind*, the grooved edge of the vomer. Its surface is marked by numerous canals for vessels and nerves, and the groove for the nasopalatine nerve, and is traversed by sutures connecting the bones of which it is formed.

The **outer or lateral wall** (Figs. 81 and 104) is formed, in *front*, by the nasal

process of the maxilla and lacrimal bones; in the *middle*, by the ethmoid and inner surface of the body of the maxilla and turbinated bone; *behind*, by the vertical plate of the palate bone; and the internal pterygoid plate of the sphenoid. Upon

FIG. 105.—Coronal section through the frontal sinus and nasal fossa. (Poirier and Charpy.)

FIG. 106.—Inner wall of nasal fossae, or septum of nose.

this outer wall are two marked projections of bone (Figs. 81 and 104). One is known as the **turbinated bone** and the other as the **middle turbinated process**. The **superior turbinated process** appears as a less distinct bony projection. This surface presents three irregular longitudinal passages, termed the superior, middle, and inferior meatuses of the nose (Figs. 104 and 105). The **superior meatus** (*meatus nasi superior*), the smallest of the three, is situated at the upper and back part of each nasal fossa, occupying the posterior third of the outer wall. It is situated between the superior and middle turbinated processes, and has opening into it two foramina, the **sphenopalatine foramen** at the back of its outer wall, and the **posterior ethmoidal cells** at the front part of the outer wall. The sphenoidal sinus opens into a recess, the **spheno-ethmoidal recess** (*recessus sphenoethmoidalis*), which is situated above and behind the superior turbinated process. The **middle meatus** (*meatus nasi medius*) is situated external to the middle turbinated process, and above the turbinated bone, and extends from the anterior end of the turbinated to the sphenopalatine foramen of the outer wall of the nasal fossa. Anteriorly it terminates in a depression, the **atrium of the nasal meatus**. The middle meatus presents in front the orifice of the **infundibulum** (*infundibulum ethmoidale*), by which the middle meatus communicates with the anterior ethmoidal cells, and through these with the frontal sinuses. The posterior ethmoidal cells also open into this meatus, while at the centre of the outer wall is the **orifice of the maxillary antrum** which varies somewhat as to its exact position in different skulls. The **inferior meatus**, the largest of the three, is the space between the turbinated bone and the floor of the nasal fossa. It extends along the entire length of the outer wall of the nose, is broader in front than behind, and presents anteriorly the lower **orifice of the canal for the nasal duct**.

Development of the Skull.—Up to a certain stage the development of the skull corresponds with that of the vertebral column; but it is modified later in association with the expansion of the brain vesicles, the formation of the organs of smell, sight, and hearing, and the development of the mouth and pharynx.

The notochord extends as far forward in the base of the future skull as the anterior end of the mid-brain, and becomes partly surrounded by mesoderm (Fig. 107). The posterior part of this mesodermal investment corresponds with the future basiocciput, and shows a subdivision into four segments, which are separated by the roots of the hypoglossal nerve. The mesoderm then extends over the brain vesicles, and thus the entire brain is enclosed by a mesodermal investment, which is termed the **membranous primordial cranium**. From the inner layer of this the bones of the skull and the membranes of the brain are developed; from the outer layer the muscles, blood-vessels, true skin, and subcutaneous tissues of the scalp. In the shark and dog-fish this membranous cranium undergoes complete chondrification, and forms the cartilaginous skull, or **chondrocranium**, of these animals. In mammals, on the other hand, the process of chondrification is limited to the base of the skull—the roof and sides being covered in by membrane. Thus, the bones of the base of the skull are preceded by cartilage, those of the roof and sides by membrane. The posterior part of the base of the skull is developed around the notochord, and exhibits a segmented condition analogous to that of the vertebral column, while the anterior part arises in front of the notochord and shows no regular segmentation. The base of the skull may therefore be divided into (a) a **chordal** or **vertebral**, and (b) a **prechordal** or **prevertebral** portion.

In the lower vertebrates two pairs of cartilages are developed, viz., a pair of parachordal cartilages, one on either side of the notochord; and a pair of prechordal cartilages, the *trabeculae*

FIG. 107.—Sagittal section of cephalic end of notochord. (Furness).

cranii, in front of the notochord (Fig. 108). The *parachordal cartilages* (Fig. 109) unite to form a cartilaginous plate, from which the cartilaginous part of the occipital bone and the basi-sphenoid are developed. On the lateral aspect of the parachordal cartilages the *otic* or *auditory vesicles* are situated, and the mesoderm enclosing them is soon converted into cartilage, forming

FIG. 108.—Diagrams of the cartilaginous cranium. (Wiedersheim.)

FIG. 109.—Model of the chondrocranium of a human embryo, 8 cm. The membrane bones are not represented. (From Hertwig's Handbuch der Entwicklungslehre.)

the *cartilaginous ear capsules*. These cartilaginous ear capsules, which are of an oval shape, fuse with the lateral aspects of the basilar plate, and from them arise the petromastoid portions of the temporal bones. The *trabeculae cranii* (Fig. 108) are two curved bars of cartilage which embrace the pituitary body; their posterior ends soon unite with the basilar plate, while their

anterior ends join to form the *ethmoidal plate*, which extends forward between the forebrain and the olfactory pits. Later, the trabeculae meet and fuse below the pituitary body, forming the floor of the pituitary fossa, and so cutting off the anterior lobe of the pituitary body from the stomatodeum. The mesal part of the ethmoidal plate forms the bony and cartilaginous parts of the nasal septum. From the lateral margins of the trabeculae cranii three processes grow out on either side. The anterior forms the lateral mass of the ethmoid and the alar cartilages of the nose; the middle gives rise to the lesser wing of the sphenoid, while from the posterior the greater wing and external pterygoid plate of the sphenoid are developed (Figs. 109 and 110). The bones of the vault are of membranous formation, and are termed *dermal* or *covering bones*. They are partly developed from the mesoderm of the primordial cranium, and partly from that which lies outside the entoderm of the foregut. They comprise the upper part of the tabular portion of the occipital (interparietal), the squamous temporals and tympanic plates, the parietals, the frontal, the vomer, the internal pterygoid plates, and the bones of the face. Some of them remain distinct throughout life (*e. g.*, parietal and frontal), while others join with the bones of the chondrocranium (*e. g.*, interparietal, squamous temporals, and internal pterygoid plates).

FIG. 110.—The same model as shown in Fig. 109 from the left side. Certain of the membrane bones of the right side are represented in yellow.

Recent observations have shown that, in mammals, the basicranial cartilage, both in the chordal and prechordal regions of the base of the skull, is developed as a single plate, which extends from behind forward. In man, however, its posterior part shows an indication of its being developed from two chondrifying centres which fuse rapidly in front and below. The relation of this cartilaginous plate to the notochord differs in different animals. In the rat embryo it lies ventrad of the notochord (Robinson); in the sheep, pig, calf, and ferret the cranial part of the notochord is enclosed within it; in man, the anterior and posterior thirds of the cartilage surround the notochord, but its middle third lies on the dorsal aspect of the notochord, which in this region is placed between the cartilage and the wall of the pharynx.

Differences in the Skull Due to Age.—At *birth* the skull as a whole is large in proportion to the other parts of the skeleton, but its facial portion is small, and equals only about one-eighth of the bulk of the cranium as compared with one-half in the adult. The frontal and parietal eminences are prominent, and the greatest width of the skull is at the level of the latter; on the other hand, the glabella, superciliary ridges, and mastoid processes are not developed. Ossification of the skull bones is not completed, and many of them—*e. g.*, the occipital, temporals, sphenoid, frontal, and mandible—consist of more than one piece. Unossified membranous intervals, termed *fontanelles*, are seen at the angles of the parietal bones; these fontanelles are *six* in number; *two*, an anterior and a posterior, are situated in the middle line, and *four*, two on each side, an antero-lateral and a postero-lateral, are placed on either side.

The *anterior* or *bregmatic fontanelle* (Fig. 111) is the largest, and is situated at the junction of the sagittal, coronal, and interfrontal sutures; it is lozenge-shaped, and measures about an inch and a half in its antero-posterior and an inch in its transverse diameter. The *posterior fontanelle* is triangular in form and is situated at the junction of the sagittal and lambdoid sutures. The *lateral fontanelles* (Fig. 112) are small, irregular in shape, and correspond respectively with the antero-inferior and postero-inferior angles of the parietal bones. An additional fontanelle is sometimes seen in the sagittal suture at the region of the obelion. The fontanelles are usually

closed by the growth and extension of the bones which surround them, but sometimes they are the sites of separate ossific centres which develop into Wormian bones. The posterior and lateral fontanelles are obliterated within a month or two after birth, but the anterior is not completely closed until the first half of the second year; sometimes it remains open beyond the second year, a condition which is usually seen in rhachitis, and is due to malnutrition. A knowledge of the shape and position of the fontanelles is of service to the accoucheur in enabling him to determine which part of the fetal head is presenting during parturition.

The small size of the face at birth is mainly accounted for by the rudimentary condition of the jaws, the noneruption of the teeth, and the small size of the maxillary air sinuses and nasal cavities. At birth the nasal cavities lie almost entirely between the orbits, and the lower border of the anterior nasal aperture is only a little below the level of the orbital floor. With the eruption of the milk teeth there is an enlargement of the face and jaws, and these changes are still more marked after the second dentition.

FIG. 111.—Skull at birth, showing the anterior and posterior fontanelles.

FIG. 112.—The lateral fontanelles.

The skull grows rapidly from birth to the seventh year, by which time the foramen magnum and petrous parts of the temporals have reached their full size and the orbital cavities are only a little smaller than those of the adult. Growth is slow from the seventh year until the approach of puberty, when a second period of activity takes place; this consists of an increase in all directions, but it is especially marked in the frontal and facial regions, where it is associated with the development of the air sinuses.

Obliteration of the Sutures.—Obliteration of the sutures of the vault takes place as age advances, usually beginning during the fourth decade of life and first becoming manifest on the inner surface, appearing externally about ten years later; the posterior part of the sagittal suture is usually the first to become obliterated, next the coronal, and then the lambdoid. The most striking feature of an old skull is the marked diminution in the size of the jaws consequent on the loss of the teeth and the absorption of the alveolar processes, thus reducing the facial height and altering the mandibular angles.

Differences in the Skull Due to Sex.—Until the age of puberty little difference exists between the male and the female skull. The skull of an adult female is, as a rule, lighter and smaller. While the cranial capacity of white males averages 1560 c.c., that of females is nearly 200 c.c. less. The female skull has thinner walls, its ridges for muscle attachment are less strongly marked, the superciliary ridges, glabella, and mastoid processes are less prominent, and the corresponding air sinuses are smaller. The upper margin of the orbit is sharper, the frontal and parietal eminences are more prominent, and the vault is somewhat flattened as compared with the male skull. The contour of the face is more rounded, the facial bones are smoother, and the jaws and teeth are smaller.

No single structural characteristic, however, serves to determine the sex, and the features enumerated above can guide in the examination only when they are sufficiently pronounced to justify a probable diagnosis.¹

¹ See P. J. Möbius: Ueber die Verschiedenheit männlicher und weiblicher Schädel. *Archiv für Anthropologie*, 1907, N. F., vol. vi.

Supernumerary, Wormian,¹ Sutural, or Epactal Bones (Ossa Triquetra).

In addition to the constant centres of ossification of the skull, additional ones are occasionally found in the course of the sutures. These form irregular, isolated bones, interposed between the cranial bones, and have been termed **Wormian bones**, or *ossa triquetra*. They are most frequently found in the course of the lambdoid suture, but occasionally also occupy the situation of the fontanelles, especially the posterior and, more rarely, the anterior. Frequently one is found between the anterior inferior angle of the parietal bone and the greater wing of the sphenoid, the **epipteric bone**, or the **pterion ossicle** (Fig. 113). They have a great tendency to be symmetrical on the two sides of the skull, and they vary much in size, being in some cases not larger than a pin's head, and confined to the outer table; in other cases so large that one pair of these bones may form the whole of the occipital bone above the superior curved lines.

FIG. 113.—Wormian bones.

Craniology.

Skulls vary in shape and size, and the term *craniology* is applied to the comparative study of these variations. By means of exact measurements and their correlation, skulls may be classified in various ways.

I. According to capacity, measured by means of shot, mustard seed, etc.

1. *Microcephalic*, with a capacity of less than 1350 c.c. (e. g., Australians, Andamanese).
2. *Mesocephalic*, with a capacity of from 1350 c.c. to 1450 c.c. (e. g., Negroes, Chinese).
3. *Megacephalic*, with a capacity of over 1450 c.c. (e. g., Europeans, Japanese, and Eskimos).

II.—To facilitate regional description and to compare the normæ of one skull with those of another, the skull is placed in such a way that a plane passing through the inferior margin of the orbit and the superior margin of the external auditory meatus shall be horizontal (the horizontal line of the Frankfort agreement). Various linear and arc measurements are made between definite and easily localized points on the surface of the skull, and, although previously described, are here tabulated for convenience of reference. They are divided into two groups: (1) those in the mesal plane, and (2) those on either side of it.

The Points in the Mesal Plane are:

Mental Point.—The most prominent point of the chin.

Alveolar Point, or Prosthion.—The central point of the anterior margin of the upper alveolar arch.

Subnasal Point.—The middle of the lower border of the anterior nasal aperture, at the base of the nasal spine.

Nasion.—The central point of the frontonasal suture.

Glabella.—The point in the middle line at the level of the superciliary ridges.

Ophryon.—The point in the middle line at the level where the temporal lines most nearly approach each other.

Bregma.—The meeting point of the coronal and sagittal sutures.

Obelion.—A point in the sagittal suture on a level with the parietal foramina.

Lambda.—The point of junction of the sagittal and lambdoid sutures.

¹ Wormius, a physician of Copenhagen, is said to have given the first detailed description of these bones.

Occipital Point.—The point in the middle line of the occipital bone farthest from the glabella.

Inion.—The external occipital protuberance.

Opisthion.—The mid-point of the posterior margin of the foramen magnum.

Basion.—The mid-point of the anterior margin of the foramen magnum.

The Points on Either Side of the Mesal Plane are:

Gonion.—The outer margin of the angle of the mandible.

Dacryon.—The point of union of the antero-superior angle of the lacrimal with the frontal bone and the frontal process of the maxilla.

Stephanion.—The point where the temporal line intersects the coronal suture.

Pterion.—The point where the greater wing of the sphenoid joins the antero-inferior angle of the parietal.

Auricular Point.—The centre of the orifice of the external auditory meatus.

Asterion.—The point of meeting of the lambdoid, masto-occipital, and mastoparietal sutures.

FIG. 114.—Brachycephalic cranium. (Poirier and Charpy.)

FIG. 115.—Dolichocephalic cranium (Poirier and Charpy.)

FIG. 116.—Brachycephalic cranium. (Poirier and Charpy.)

FIG. 117.—Dolichocephalic cranium. (Poirier and Charpy.)

The *horizontal circumference* of the cranium is measured in a plane passing through the glabella (Turner) or the ophryon (Flower) in front, and the occipital point behind; it averages about twenty inches (50 cm.) in the female and twenty-one inches (52.5 cm.) in the male.

The *occipitofrontal or longitudinal arc* is measured from the nasion over the middle line of the vertex to the opisthion; while the *basinasal length* is the distance between the basion and the nasion. These two measurements, plus the antero-posterior diameter of the foramen magnum, represent the *vertical circumference* of the cranium.

The *length* is measured from the glabella to the occipital point, while the *breadth*, or greatest transverse diameter, is usually found near the external auditory meatus. The proportion of breadth to length $\frac{(\text{breadth} \times 100)}{\text{length}}$ is termed the *cephalic index*, or *index of breadth*.

The *height* is usually measured from the basion to the bregma, and the proportion of height to length $\frac{(\text{height} \times 100)}{\text{length}}$ constitutes the *vertical* or *height index*.

In studying the face the principal points to be noticed are the proportion of its length and breadth, the shape of the orbits and of the anterior nasal aperture, and the degree of projection of the jaws.

The *length of the face* may be measured from the ophryon or nasion to the chin, or, if the mandible be wanting, to the alveolar point; while its *width* is represented by the distance between the zygomatic arches. By comparing the length with the width of the face, skulls may be divided into two groups—*dolichofacial*, or *leptoprosope* (long-faced), and *brachyfacial*, or *chemoprosope* (short-faced).

The *orbital index* signifies the proportion which the orbital height bears to the orbital width, thus:

$$\frac{\text{orbital height} \times 100}{\text{orbital width}}$$

The *nasal index* expresses the proportion which the width of the anterior nasal aperture bears to the height of the nose, the latter being measured from the nasion to the lower margin of the nasal aperture, thus:

$$\frac{\text{nasal width} \times 100}{\text{nasal height}}$$

The degree of projection of the jaws is determined by the *gnathic* or *alveolar index*, which represents the proportion between the basialveolar and basinasal lengths, thus:

$$\frac{\text{basialveolar length} \times 100}{\text{basinasal length}}$$

The following table, modified from that given by Duckworth, illustrates how these different indices may be utilized in the classification of skulls.

Index.	Classification.	Nomenclature.	Examples.
1. Cephalic . . .	Below 75 Between 75 and 80 Above 80	Dolichocephalic Mesaticephalic Brachycephalic	Kaffirs and Native Australians Europeans and Chinese Mongolians and Andamans
2. Orbital . . .	Below 84 Between 84 and 89 Above 89	Microseme Mesoseme Megaseme	Tasmanians and Native Australians Europeans Chinese and Polynesians
3. Nasal . . .	Below 48 Between 48 and 53 Above 53	Leptorhine Mesorhine Platyrrhine	Europeans Chinese and Japanese Negroes and Native Australians
4. Gnathic . . .	Below 98 Between 98 and 103 Above 103	Orthognathous Mesognathous Prognathous	Europeans Chinese and Japanese Native Australians

Surface Form.—The various bony prominences or landmarks which are to be easily felt and recognized in the head and face, and which afford the means of mapping out the important structures comprised in this region, are as follows:

1. Supraorbital arch.
2. Internal angular process.
3. External angular process.
4. Zygomatic arch.
5. Mastoid process.
6. External occipital protuberance.
7. Superior curved line of occipital bone.
8. Parietal eminences.
9. Temporal ridge.
10. Frontal eminences.
11. Superciliary ridges.
12. Nasal bones.
13. Lower margin of orbit.
14. Mandible.

(1) The **supraorbital arches** are to be felt throughout their entire extent, covered by the eyebrows. They form the upper boundary of the circumference or base of the orbits, and separate

the face from the forehead. They are strong and arched, and terminate internally on each side of the root of the nose in the internal angular process, which articulates with the lacrimal bone. Externally they terminate in the external angular process, which articulates with the malar bone. This arched ridge is sharper and more defined in its outer than in its inner half, and forms an overhanging process which protects and shields the lacrimal gland. It thus protects the eye in its most exposed situation and in the direction from which blows are most likely to descend. The supraorbital arch varies in prominence in different individuals. It is more marked in the male than in the female, and in some races of mankind than others. In the less civilized races, as the forehead recedes backward, the supraorbital arch becomes more prominent, and approaches more to the characters of the monkey tribe, in which the supraorbital arches are very largely developed, and acquire additional prominence from the oblique direction of the frontal bone. (2) The **internal angular process** is scarcely to be felt. Its position is indicated by the angle formed by the supraorbital arch with the nasal process of the maxilla and the lacrimal bone at the inner side of the orbit. Between the internal angular processes of the two sides is a broad surface which assists in forming the root of the nose, and immediately above this a broad, smooth, somewhat triangular surface, the **glabella**, situated between the superciliary ridges. (3) The **external angular process** is much more strongly marked than the internal, and is plainly to be felt. It is formed by the junction or confluence of the supraorbital and temporal ridges, and, articulating with the malar bone, it serves to a very considerable extent to support the bones of the face. In carnivorous animals the external angular process does not articulate with the malar, and therefore this lateral support to the bones of the face is not present. (4) The **zygomatic arch** is plainly to be felt throughout its entire length, being situated almost immediately under the skin. It is formed by the malar bone and the zygomatic process of the temporal bone. At its anterior extremity, where it is formed by the malar bone, it is broad and forms the prominence of the cheek; the posterior part is narrower, and terminates just in front and a little above the tragus of the external ear. The lower border is more plainly to be felt than the upper, in consequence of the dense temporal fascia being attached to the latter, which somewhat obscures its outline. Its shape differs very much in individuals and in different races of mankind. In the skulls of savages—as, for instance, in the skull of the negro of the Guinea Coast—the malar bones project forward and not outward, and the zygoma at its posterior extremity extends farther outward before it is twisted on itself to be prolonged forward. This makes the zygomatic arch stand out in bold relief, and affords greater space for the Temporal muscle. In skulls which have a more pyramidal shape, as in the Eskimos or Greenlanders, the malar bones do not project forward and downward under the eyes, as in the preceding form, but take a direction outward, forming with the zygoma a large, rounded sweep or segment of a circle. Thus it happens that if two lines are drawn from the zygomatic arches, touching the temporal ridges, they meet above the top of the head, instead of being parallel, or nearly so, as in the European skull, in which the zygomatic arches are not nearly so prominent. This gives to the face a more or less oval type. (5) Behind the ear is the **mastoid portion of the temporal bone**, plainly to be felt, and terminating below in a nipple-shaped process. Its anterior border can be traced immediately behind the concha, and its apex is on about a level with the lobule of the ear. It is rudimentary in infancy, but gradually develops in childhood, and is more marked in the negro than in the European. (6) The **external occipital protuberance (inion)** is always plainly to be felt just at the level where the skin of the neck joins that of the head. At this point the skull is thick for the purposes of safety, while radiating from it are numerous curved arches or buttresses of bone which give to this portion of the skull further security. (7) Running outward on either side from the external occipital protuberance is an arched ridge of bone, which can be more or less plainly perceived. This is the **superior curved line of the occipital bone**, and gives attachment to some of the muscles which keep the head erect on the vertebral column; accordingly, we find it more developed in the negro tribes, in whom the jaws are much more massive, and therefore require stronger muscles to prevent their extra weight carrying the head forward. Below this line the surface of bone at the back of the head is obscured by the overlying muscles. Above it the vault of the cranium is thinly covered with soft structures, so that the form of this part of the head is almost exactly that of the upper portion of the occipital, the parietal, and the frontal bones themselves; and in bald persons, even the lines of junction of the bones, especially the junction of the occipital and parietal at the lambdoid suture, may be defined as a slight depression caused by the thickening of the borders of the bones in this situation. (8) In the line of the greatest transverse diameter of the head, on each side of the middle line, are generally to be found the **parietal eminences**, one on each side of the middle line, though sometimes these eminences are not situated at the point of the greatest transverse diameter, which is at some other prominent part of the parietal region. They denote the point where ossification of the parietal bone began. They are much more prominent and well marked in early life, in consequence of the sharper curve of the bone at this period, so that it describes the segment of a smaller circle. Later in life, as the bone grows, the curve spreads out and forms the segment of a larger circle, so that the eminence becomes less distinguishable. In consequence of this sharp curve of the bone in early life, the whole of the vault of the skull has a squarer shape than it has in later life, and this appear-

ance may persist in those suffering from rachitis. The eminence is more apparent in the negro's skull than in that of the European. This is due to greater flattening of the temporal fossa in the former skull to accommodate the larger Temporal muscle which exists in these races. The parietal eminence is particularly exposed to injury from blows or falls on the head, but fracture is to a certain extent prevented by the shape of the bone, which forms an arch, so that the force of the blow is diffused over the bone in every direction. (9) At the side of the head may be felt the **temporal ridge**. Commencing at the external angular process, it may be felt as a curved ridge, passing upward and then curving backward, on the frontal bone, separating the forehead from the temporal fossa. It may then be traced passing backward in a curved direction, over the parietal bone, and, though less marked, still generally to be recognized. Finally, the ridge curves downward, and terminates in the posterior root of the zygoma, which separates the squamous from the subcutaneous mastoid portion of the temporal bone. (10) The **frontal eminences** vary a good deal in different individuals, being considerably more prominent in some than in others, and they are often not symmetrical on the two sides of the body, the one being much more pronounced than the other. This is often especially noticeable in the skull of the young child or infant, and becomes less marked as age advances. The prominence of the frontal eminences depends more upon the general shape of the whole bone than upon the size of the protuberances themselves. As the skull is more highly developed in consequence of increased intellectual capacity, so the frontal bone becomes more upright and the frontal eminences stand out in bolder relief. Thus they may be considered as affording, to a certain extent, an indication of the development of the hemispheres of the cerebrum beneath, and of the mental powers of the individual. They are not so much exposed to injury as the parietal eminences. In falls forward the upper extremities are involuntarily thrown out, and break the force of the fall, and thus shield the frontal bone from injury. (11) Below the frontal eminences on the forehead are the **superciliary ridges**, which denote the position of the frontal sinuses, and vary according to the size of the sinuses in different individuals, being, as a rule, small in the female, absent in children, and sometimes unusually prominent in the male, when the frontal sinuses are largely developed. They commence on either side of the glabella, and at first present a rounded form, which gradually fades away at their outer ends. (12) The **nasal bones** form the prominence of the nose. They vary much in size and shape, and to them are due the variations in contour of this organ and much of the character of the face. Thus, in the Mongolian or Ethiopian they are flat, broad, and thick at their base, giving to these races the flattened nose by which they are characterized, and differing very decidedly from the Caucasian, in whom the nose, owing to the shape of the nasal bones, is narrow, elevated at the bridge, and elongated downward. Below, the nasal bones are thin and connected with the cartilages of the nose, and the angle or arch formed by their union serves to throw out the bridge of the nose, and is much more marked in some individuals than others. (13) The **lower margin of the orbit**, formed by the maxilla and the malar bone, is plainly to be felt throughout its entire length. It is continuous internally with the nasal process of the maxilla, which forms the inner boundary of the orbit. At the point of junction of the lower margin of the orbit with the nasal process is to be felt a little tubercle of bone, which can be plainly perceived by running the finger along the bone in this situation. This tubercle serves as a guide to the position of the lacrimal sac, which is situated above and behind it. (14) The outline of the **mandible** may be felt throughout its entire length. Just in front of the tragus of the external ear, and below the zygomatic arch, the condyle can be made out. When the mouth is opened this prominence of bone can be perceived advancing out of the glenoid fossa on to the eminentia articularis, and receding again when the mouth is closed. From the condyle the posterior border of the ramus can be felt extending down to the angle. A line drawn from the condyle to the angle would indicate the exact position of this border. From the angle to the symphysis of the chin the lower, rounded border of the body of the bone may be plainly felt. At the point of junction of the two halves of the bone is a well-marked triangular eminence, the **mental process**, which forms the prominence of the chin.

Applied Anatomy.—The thickness of the skull varies greatly in different regions of the same skull and in different individuals. The average thickness of the skullcap is about one-fifth of an inch (5 mm.). The thickest portions are the occipital protuberance, the inferior portion of the frontal bone, and the mastoid process. The thinnest portions are the occipital fossæ, the squamous portion of the temporal bone, and over certain sinuses and arteries. An arrest in the ossifying process may give rise to deficiencies or gaps, or to fissures, which are of importance in a medicolegal point of view, as they are liable to be mistaken for fractures. The fissures generally extend from the margin toward the centre of the bone, but gaps may be found in the middle as well as at the edges. In course of time they may become covered with a thin lamina of bone.

Occasionally a protrusion of the brain or its membranes may take place through one of these gaps in an imperfectly developed skull. When the protrusion consists of membranes only, and is filled with cerebrospinal fluid, it is called a **meningocele**; when the protrusion consists of brain as well as membranes, it is termed an **encephalocele**; and when the protruded brain is a prolongation from one of the ventricles, and is distended by a collection of fluid from an accumulation in the ventricle, it is termed a **hydrancephalocele**. This latter condition is some-

times found at the root of the nose, where a protrusion of the anterior horn of the lateral ventricle takes place through a deficiency of the frontonasal suture. These malformations are usually found in the middle line, and most frequently at the back of the head, the protrusion taking place through the fissures which separate the four centres of ossification from which the tabular portion of the occipital bone is originally developed (see page 73). They most frequently occur through the upper part of the vertical fissure, which is the last to ossify, but not uncommonly through the lower part, when the foramen magnum may be incomplete. More rarely these protrusions have been met with in other situations than those above mentioned, both through normal fissures, as the sagittal, lambdoid, and other sutures, and also through abnormal gaps and deficiencies at the sides, and even at the base of the skull. Force may be responsible in a young person for *separating a suture*. This accident, seldom met with even in the young, is only occasionally encountered in older persons.

Fractures of the skull may be divided into those of the *vault* and those of the *base*. Fractures of the vault are usually produced by direct violence. This portion of the skull varies in thickness and strength in different individuals, but, as a rule, is sufficiently strong to resist a very considerable amount of violence without being fractured. This is due to several causes—the rounded shape of the head and its construction of a number of secondary elastic arches, each made up of a single bone; the fact that it consists of a number of bones, united at all events in early life by a sutural ligament, which acts as a sort of buffer and interrupts the continuity of any violence applied to the skull; the presence of arches or ridges, both on the inside and outside of the skull, which materially strengthen it; and the mobility of the head upon the vertebral column, which further enables it to withstand violence. The elasticity of the bones of the head is especially marked in the skull of the child, and this fact, together with the wide separation of the individual bones from each other, and the interposition between them of other and softer structures render fracture of the bones of the head a very uncommon event in infants and quite young children; as age advances and the bones become joined, fracture is more common, though still less liable to occur than in the adult. Fractures of the vault may, and generally do, involve the *whole thickness* of the bone; but sometimes one table may be fractured without any corresponding injury to the other. Thus, the *outer table* of the skull may be splintered and driven into the diploë, or in the frontal or mastoid regions into the frontal or mastoid cells, without any injury to the internal table. And on the other hand, the *internal table* has been fractured, and portions of it depressed and driven inward, without any fracture of the outer table. As a rule, in fractures of the skull the inner table is more splintered and comminuted than the outer, and this is due to several causes. It is thinner and more brittle; the force of the violence as it passes inward becomes broken up, and is more diffused by the time it reaches the inner table; the bone, being in the form of an arch, bends as a whole and spreads out, and thus presses the particles together on the convex surface of the arch—i. e., the outer table—and forces them asunder on the concave surface or inner table; and lastly, there is nothing firm under the inner table to support it and oppose the force. *Fractures of the vault* may be *simple fissures* or *starred* and *comminuted fractures*, and these may be *depressed* or *elevated*. These latter cases of fracture with elevation of the fractured portion are uncommon, and can only be produced by direct wound. In comminuted fracture a portion of the skull is broken into several pieces, the lines of fracture radiating from a centre where the chief impact of the blow was felt; if depressed, a fissure circumscribes the radiating line, enclosing a portion of skull. If this area is circular, it is termed a **pond fracture**, and would in all probability have been caused by a round instrument, as a blackjack or hammer; if elliptical in shape, it is termed a **gutter fracture**, and would owe its shape to the instrument which had produced it, as a poker. A fracture may take place along the line of an ossified or partly ossified suture. When a surgeon explores the vault of the skull through a wound he must not mistake a Wormian bone for a fragment produced by a fracture. A Wormian bone which may lead to mistake is encountered at the anterior inferior angle of the parietal bone. Wormian bones are most frequently found along the lambdoid suture.

Fractures of the base are most frequently produced by the extension of a fissure from the vault, as in falls on the head, where the fissure starts from the part of the vault which first struck the ground. Sometimes, however, they are caused by direct violence, when foreign bodies have been forced through the thin roof of the orbit, through the cribriform plate of the ethmoid from being thrust up the nose, or through the roof of the pharynx. Other cases of fracture of the base occur from indirect violence, as in fracture of the occipital bone from impaction of the spinal column against its condyles in falls on the buttocks, knees, or feet, or in cases where the glenoid cavity has been fractured by the violent impact of the condyle of the mandible against it from blows on the chin.

The most common place for fracture of the base to occur is through the middle fossa, and here the fissure usually takes a fairly definite course. Starting from the point struck, which is generally somewhere in the neighborhood of the parietal eminence, it runs downward through the parietal bone and the squamous portion of the temporal bone and across the petrous portion of this bone, frequently traversing and implicating the internal auditory meatus, to the middle

lacerated foramen. From this it may pass across the body of the sphenoid, through the pituitary fossa to the middle lacerated foramen of the other side, and may indeed travel round the whole cranium, so as completely to separate the anterior from the posterior part. The course of the fracture should be borne in mind, as it explains the symptoms to which fracture in this region may give rise; thus, if the fissure pass across the internal auditory meatus, injury to the facial and auditory nerves may result, with consequent facial paralysis and deafness; or the tubular prolongation of the arachnoid around these nerves in the meatus may be torn, and thus permit of the escape of the cerebrospinal fluid should there be a communication between the internal ear and the tympanum and the membrana tympani be ruptured, as is frequently the case; again, if the fissure passes across the pituitary fossa and the mucoperiosteum covering the under surface of the body of the sphenoid is torn, blood will find its way into the pharynx and be swallowed, and after a time vomiting of blood will result. Fractures of the anterior fossa, involving the bones forming the roof of the orbit and nasal fossa, are generally the results of blows on the forehead; but fracture of the cribriform plate of the ethmoid may be a complication of fracture of the nasal bone. When the fracture implicates the roof of the orbit, the blood finds its way into this cavity, and, travelling forward, appears as a subconjunctival ecchymosis. Subconjunctival ecchymosis can also be caused by fracture of the malar bone. If the roof of the nasal fossa be fractured, the blood escapes from the nose. In rare cases there may be also escape of cerebrospinal fluid from the nose where the dura and arachnoid have been torn. In fractures of the posterior fossa extravasation of blood takes place beneath the deep fascia, and discoloration of the skin is soon observed in the course of the posterior auricular artery, the discoloration first appearing in the skin over the tip of the mastoid process of the temporal bone (**Battle's sign**). Some of the blood which was extravasated beneath the deep fascia approaches the surface through the openings in the deep fascia for the passage of vessels and nerves.

The bones of the skull are frequently the seat of nodes, and not uncommonly **necrosis** results from this cause, also from injury. Necrosis may involve the entire thickness of the skull, but is usually confined to the external table. Necrosis of the internal table alone is rarely met with. The bones of the skull are also sometimes the seat of *sarcomatous tumors*.

The skull in *rhachitis* is peculiar—the forehead is high, square, and projecting, and the antero-posterior diameter of the skull is long in relation to the transverse diameter. The bones of the face are small and ill-developed, and this gives the appearance of a larger head than actually exists. The bones of the head are often thick, especially in the neighborhood of the sutures, and the anterior fontanelle is late in closing, sometimes remaining unclosed until the fourth year. The condition of *craniotabes* has by some been also believed to be the result of *rhachitis*, by others is believed to be due to inherited syphilis. In all probability it is due to both. In these cases the bone undergoes atrophic changes in patches, so that it becomes greatly thinned in places, generally where there is pressure, as from the pillow or nurse's arm. It is, therefore, usually met with in the parietal bone and vertical plate of the occipital bone.

In *congenital syphilis* deposits of porous bone are often found at the angles of the parietal bones and two halves of the frontal bone which bound the anterior fontanelle. These deposits are separated by the coronal and sagittal sutures, and give to the skull the appearance of a hot cross bun. They are known as *Parrot's nodes*, and such a skull has received the name of **natiform**, from its fancied resemblance to the buttocks. The cells of the mastoid are sometimes the seat of suppuration as the result of infection extending backward from the tympanic cavity. In such cases the antrum of the mastoid must be opened in order that the pus escape. This is done by applying the gouge between the posterior wall of the external auditory meatus and the posterior root of the zygoma. This space is called the *suprameatal triangle* of *MacEwan*.

In connection with the bones of the face a common malformation is **cleft palate**, owing to the nonunion of the palatal processes of the maxillary or preoral arch. This cleft may involve

FIG. 118.—Division of the mastoid process into four equal parts. An opening in the upper anterior quadrant reaches the mastoid antrum; into the upper posterior quadrant reaches the lateral sinus; the lower anterior quadrant into mastoid cells; a superficial opening into the lower posterior quadrant reaches mastoid cells; a deep opening reaches the descending limb of the lateral sinus. (A. E. Schmitt.)

the whole or only a portion of the hard palate, and usually involves the soft palate also. The cleft is in the middle line, except it involves the alveolus in front, when it follows the suture between the main portion of the bone and the premaxillary bone. Sometimes the cleft runs on either side of the premaxillary bone, so that this bone is quite isolated from the maxillary bones and hangs from the end of the vomer. In such a case the premaxillary bone usually contains the germs of the central incisors only. In some cases there is no premaxillary bone and the great gap in the lip is in the median line. Cleft palate (page 106) is usually associated with harelip, which, when single, is almost always on one side, corresponding to the position of the suture between the lateral incisor and canine tooth. Some few cases of median harelip have been described. In double harelip there is a cleft on each side of the middle line.

The outlines and the height of the arch of the palate vary greatly in different persons. A narrow palate with a high arch is common in idiots and certain degenerates.

The bones of the face are sometimes fractured as the result of direct violence. The two most commonly broken are the nasal bone and the mandible, and of these, the latter is by far the most frequently fractured of all the bones of the face. Fracture of the *nasal* bone is for the most part transverse, and takes place about half an inch from the free margin. The broken portion may be displaced backward or more generally to one side by the force which produced the lesion, as there are no muscles here which can cause displacement. The *malar* bone is probably never broken alone; that is to say, unconnected with a fracture of the other bones of the face. The *zygomatic arch* is occasionally fractured, and when this occurs from direct violence, as is usually the case, the fragments may be displaced inward. This lesion is often attended with great difficulty, or even inability to open and shut the mouth, and this has been stated to be due to the depressed fragments perforating the temporal muscle, but would appear rather to be caused by the injury done to the bony origin of the Masseter muscle. *Fractures of the maxilla* may vary much in degree, from the chipping off of a portion of the alveolar arch, a frequent accident when the "old key" instrument was used for the extraction of teeth, to an extensive comminution of the whole bone from severe violence, as the kick of a horse. The most common situation for a *fracture of the mandible* is in the neighborhood of the canine tooth, as at this spot the jaw is weakened by the deep socket for the fang of this tooth; it is next most frequently fractured at the angle; then at the symphysis, and finally the neck of the condyle or the coronoid process may be broken. Occasionally a double fracture may occur, one in either half of the bone. The fractures are usually compound, from laceration of the mucous membrane covering the gums. The displacement is mainly the result of the same violence as produced the injury, but may be further increased by the action of the muscles passing from the neighborhood of the symphysis to the hyoid bone.

The maxilla and mandible are both of them frequently the seat of *necrosis*, though the disease affects the latter much more frequently than the former. It may be the result of periostitis, from tooth irritation, injury, or the action of some specific poison, as syphilis, or from salivation by mercury; it not infrequently occurs in children after attacks of the exanthematous fevers, and a special form occurs from the action of the fumes of phosphorus in persons engaged in the manufacture of matches.

Tumors attack the jaw bones not infrequently, and these may be either innocent or malignant; in the upper jaw cysts may occur in the antrum, constituting the so-called dropsy of the antrum; or, again, cysts may form in either jaw in connection with the teeth—either cysts connected with the roots of fully developed teeth, the "dental cyst;" or cysts connected with imperfectly developed teeth, the "dentigerous cyst." Solid innocent tumors include the fibroma, the chondroma, and the osteoma. Of malignant tumors there are the endotheliomata, the sarcomata, and the epitheliomata. The sarcomata are of various kinds, the spindle-celled, the round-celled, which are of a very malignant character, and the myeloid sarcomata, principally affecting the alveolar margin of the bone. Of the epitheliomata we find the squamous variety spreading to the bone from the palate or gum, and the cylindrical epithelioma originating in the antrum or nasal fossæ.

Both mandible and maxilla occasionally require **excision** for tumors and in some other conditions. The maxilla is removed by an incision from the inner canthus of the eye, along the side of the nose, around the ala, and down the middle line of the upper lip. A second incision is carried outward from the inner canthus of the line along the lower margin of the orbit as far as the prominence of the malar bone. The flap thus formed is reflected outward and the surface of the bone exposed, and the central incisor of the diseased side is removed. The connections of the bone to the other bones of the face are then divided with a narrow saw and bone-cutting forceps. They are (1) the junction with the malar bone, passing into the sphenomaxillary fissure; (2) the nasal process; a small portion of its upper extremity, connected with the nasal bone in front, the lacrimal bone behind, and the frontal bone above, being left; (3) the connection with the bone on the opposite side and the palate in the roof of the mouth. The bone is now firmly grasped with lion-jaw forceps, and by means of a rocking movement upward and downward the remaining attachments of the orbital plate with the ethmoid and the back of the bone with the palate, broken through. The soft palate is first separated from the hard with a scalpel, and is not

removed. Occasionally in removing the maxilla it will be found that the orbital plate can be spared, and this should always be done if possible. A horizontal saw-cut is to be made just below the infraorbital foramen and the bone cut through with a chisel and mallet. Lockwood has pointed out that in removing the maxilla the surgeon must be careful in dividing the nasal process of the maxilla to preserve the internal orbital or palpebral ligament (*Tendo oculi*), because this ligament arises from the palpebral fascia, and if it is interfered with the eye will inevitably drop downward. Removal of one-half of the mandible is sometimes required. If possible, the section of the bone should be made to one side of the symphysis, so as to save the genial tubercles and the origin of the Geniohyoglossus muscle, as otherwise the tongue tends to fall backward and may produce suffocation. Having extracted the central or preferably the lateral incisor tooth, a vertical incision is made down to the bone, commencing at the free margin of the lip, and carried to the lower border of the bone; it is then carried along its lower border to the angle and up the posterior margin of the ramus to a level with the lobule of the ear. The flap thus formed is raised by separating all the structures attached to the outer surface of the bone. The jaw is now sawed through at the point where the tooth has been extracted, and the knife passed along the inner side of the mandible, separating the structures attached to this surface. The mandible is then grasped by the surgeon and strongly depressed, so as to bring down the coronoid process and enable the operator to sever the tendon of the Temporal muscle. The mandible can be now further depressed, care being taken to not evert it nor rotate it outward, which would endanger the internal maxillary artery, and the External pterygoid muscle is torn through or divided. The capsular ligament is now opened in front and the lateral ligaments divided, and the mandible removed with a few final touches of the knife.

The antrum of Highmore occasionally requires tapping for suppuration. This may be done through the socket of a tooth, preferably the first molar, the fangs of which are most intimately connected with the antrum, or through the facial aspect of the bone above the alveolar process. This latter method does not perhaps afford such efficient drainage, but there is less chance of food finding its way into the cavity. The operation may be performed by incising the mucous membrane above the second molar tooth, and driving a trocar or any sharp-pointed instrument into the cavity.

THE HYOID OR LINGUAL BONE (OS HYOIDEUM).

The **hyoid bone** (Fig. 119) is a bony arch, shaped like a horseshoe, and consisting of five segments—a body, two greater cornua, and two lesser cornua. It is suspended from the tips of the styloid processes of the temporal bones by ligamentous bands, the stylohyoid ligaments.

The **Body**, or **basihyal** (*corpus ossei hyoidei*), forms the central part of the bone, and is of a quadrilateral form.

Surfaces.—Its **anterior surface** (Fig. 119), convex, directed forward and upward, is divided into two parts by a vertical ridge which descends along the median line and is crossed at right angles by a horizontal ridge, so that this surface is divided into four spaces or depressions. At the point of meeting of these two lines is a prominent elevation, the **tubercle**. The anterior surface gives attachment to the Geniohyoid in the greater part of its extent; *above*, to the Geniohyoglossus; *below*, to the Mylohyoid, Stylohyoid, and the aponeurosis of the Digastric (suprahyoid aponeurosis); and between these to part of the Hyoglossus. The **posterior surface** is smooth, concave, directed backward and downward, and separated from the epiglottis by the thyrohyoid membrane and by a quantity of loose areolar tissue. The **lateral surfaces** after middle

FIG. 119.—Hyoid bone. Anterior surface. (Enlarged.)

life are joined to the greater cornua. In early life they are connected with the cornua by cartilaginous surfaces, and held together by ligaments, and occasionally a synovial membrane is found between them.

Borders.—The **superior border** is rounded, and gives attachment to the thyrohyoid membrane, part of the Geniohyoglossi and Chondroglossi muscles. The **inferior border** gives attachment, in *front*, to the Sternohyoid; *behind*, to the Omohyoid and to the part of the Thyrohyoid at its junction with the great cornua. It also gives attachment to the Levator glandulae thyroideae when this muscle is present.

The **Greater Cornua** (*cornua majora*), or **thyrohyals**, project backward from the lateral surfaces of the body; they are flattened from above downward, diminish in size from before backward, and terminate posteriorly in a tubercle for the attachment of the lateral thyrohyoid ligament. The outer surface gives attachment to the Hyoglossus, their upper border to the Middle constrictor of the pharynx, their lower border to part of the Thyrohyoid muscle.

The **Lesser Cornua** (*cornua minora*), or **ceratohyals**, are two small, conical-shaped eminences attached by their bases to the angles of junction between the body and greater cornua, and giving attachment by their apices to the stylohyoid ligaments.¹ The smaller cornua are connected to the body of the bone by a distinct diarthrodial joint, which usually persists throughout life, but occasionally becomes ankylosed.

Development.—From *six* centres—two (sometimes one) for the body, and one for each cornu. Ossification commences in the body about the eighth month, and in the greater cornua toward the end of fetal life. Ossification of the lesser cornua commences in the first or second year after birth.

Attachment of Muscles.—Sternohyoid, Thyrohyoid, Omohyoid; aponeurosis of the Digastric, Stylohyoid, Mylohyoid, Geniohyoid, Geniohyoglossus, Chondroglossus, Hyoglossus, Middle constrictor of the pharynx, and occasionally a few fibres of the Inferior lingualis. It also gives attachment to the thyrohyoidean membrane and the stylohyoid, thyrohyoid, and hyoepiglottic ligaments.

Surface Form.—The hyoid bone can be felt in the receding angle below the chin, and the finger can be carried along the whole length of the bone to the greater cornu, which is situated just below the angle of the mandible. This process of bone is best perceived by making pressure on one cornu, and so pushing the bone over to the opposite side, when the cornu of this side will be distinctly felt immediately beneath the skin. This process of bone is an important landmark in ligation of the lingual artery.

Applied Anatomy.—The hyoid bone is occasionally *fractured*, generally from direct violence, as in the act of garroting or throttling. It is frequently found broken in those who have been hanged. The greater cornu is the part of the bone most frequently broken, but sometimes the fracture takes place through the body of the bone. In consequence of the muscles of the tongue having important connections with this bone, there is great pain upon any attempt being made to move the tongue, as in speaking or swallowing.

THE THORAX.

The **thorax**, or **chest**, is an osseocartilaginous cage, the cavity of which (*cavum thoracis*) contains and protects the principal organs of respiration and circulation. It is conical in shape, being narrow above and broad below, flattened from before backward, and longer behind than in front. It is somewhat reniform on transverse section.

Boundaries.—The **posterior surface** is formed by the twelve thoracic vertebræ and the posterior part of the ribs. It is concave from above downward, and presents on each side of the middle line a deep groove, the **vertebral groove**, in consequence of the direction backward and outward which the ribs take from their

¹ These ligaments in many animals are distinct bones, and in man are occasionally ossified to a certain extent.

vertebral extremities to their angles. The **anterior surface** is flattened or slightly convex, and inclined forward from above downward. It is formed by the sternum and costal cartilages. The **lateral surfaces** are convex; they are formed by the ribs, separated from each other by spaces. Each space is called an **intercostal space** (*spatium intercostale*). These are eleven in number, and are occupied by the intercostal muscles.

FIG. 120.—The thorax. Ventral view.

The **superior or upper aperture** of the thorax, the **inlet** (*apertura thoracis superior*), is reniform in shape, being broader from side to side than from before backward. It is formed by the first thoracic vertebra behind, the upper margin of the sternum in front, and the first rib on each side. It slopes downward and forward, so that the anterior boundary is on a lower level than the posterior. The antero-posterior diameter is about two inches (5 cm.), and the transverse about four (10 cm.). The parts which pass through the upper opening of the thorax are, from before backward in or near the middle line, the Sternohyoid and Sternothyroid muscles, the remains of the thymus gland, the trachea, œsophagus, thoracic duct, the inferior thyroid veins, and the Longus colli muscle

of each side; at the sides, the innominate artery, the left common carotid, and left subclavian arteries, the internal mammary and superior intercostal arteries, the right and left innominate veins, the vagus, cardiac, phrenic, and sympathetic nerves, the anterior branch of the first thoracic nerve, and the recurrent laryngeal nerve of the left side. The apex of each lung, covered by the pleura, also projects through this aperture, a little above the margin of the first rib.

FIG. 121.—The thorax. Dorsal view. (Spalteholz.)

The **inferior** or **lower opening** (*apertura thoracis inferior*) is formed by the twelfth thoracic vertebra behind, by the twelfth ribs at the sides, and in front by the eleventh, tenth, ninth, eighth, and seventh costal cartilages, which ascend on either side and form an angle, the **subcostal angle** (*angulus infrasternalis*), from the apex of which the ensiform cartilage projects. It is wider transversely than from before backward. It slopes obliquely downward and backward, so that the cavity of the thorax is much deeper behind than in front. The Diaphragm closes in the opening forming the floor of the thorax.

The Cavity of the Thorax (*cavum thoracis*).—The capacity of the cavity of the thorax does not correspond with its apparent size externally, because (1) the space enclosed by the lower ribs is occupied by some of the abdominal viscera; and (2) the cavity extends above the first rib into the neck. The size of the cavity of the thorax is constantly varying during life, with the movements of the ribs and Diaphragm, and with the degree of distention of the abdominal viscera. From the collapsed state of the lungs, as seen when the thorax is opened, in the dead body, it would appear as if the viscera only partly filled the cavity of the thorax, but during life there is no vacant space, that which is seen after death being filled up during life by the expanded lungs.

In the female the thorax differs as follows from the male: (1) Its general capacity is less. (2) The sternum is shorter. (3) The upper margin of the sternum is on a level with the lower part of the body of the third thoracic vertebra, whereas in the male it is on a level with the lower part of the body of the second thoracic vertebra. (4) The upper ribs are more movable, and so allow a greater enlargement of the upper part of the thorax than in the male.

The Sternum, or Breast Bone.

The **sternum**, or **breast bone** (Figs. 122 and 123), is a flat, narrow bone, situated in the median line of the front of the chest, and consisting, in the adult, of three portions. It has been likened to an ancient sword; the upper piece, representing the handle, is termed the **manubrium sterni** (*presternum*); the middle and largest piece, which represents the chief part of the blade, is termed the **gladiolus** (*mesosternum* or *corpus sterni*); and the inferior piece, which is likened to the point of the sword, is termed the **ensiform** or **xiphoid process** or **appendix** (*processus xiphoides* or *metasternum*). In its natural position its inclination is oblique from above downward and forward. It is slightly convex in front, concave behind, broad above, becoming narrowed at the point where the first and second pieces are connected, after which it again widens a little, and is pointed at its extremity. Its average length in the adult is about seven inches (17.5 cm.), being rather longer in the male than in the female. At the junction of the manubrium and gladiolus is a distinct angle (*angulus Ludovici*), the gladiolus looking forward, the manubrium also looking forward, but to a less degree. This angle is on a level with the second rib, and is produced by retraction of the upper portion of the thorax.

First Piece.—The first piece, or the **manubrium sterni**, is of a somewhat triangular form, broad and thick above, narrow below at its junction with the middle piece.

Surfaces.—Its **anterior surface**, convex from side to side, concave from above downward, is smooth, and affords attachment on each side to the Pectoralis major and sternal origin of the Sternomastoid muscle. In well-marked bones the ridges limiting the attachment of these muscles are very distinct. Its **posterior surface**, concave and smooth, affords attachment on each side of the Sternohyoid and Sternothyroid muscles.

Borders.—The **superior border**, the thickest, presents at its centre the **presternal notch** (*incisura jugularis*), and on each side an oval articular surface, the **clavicular facet** (*incisura clavicularis*), directed upward, backward, and outward, for articulation with the sternal end of the clavicle. The **inferior border** presents an oval, rough surface, covered in the recent state with a thin layer of cartilage, for articulation with the second portion of the bone (*synchondrosis sternalis*). The junction of the manubrium with the gladiolus is marked by a transverse ridge, which corresponds to the attachment on each side of the cartilage of the second rib. The **lateral borders** are marked above by a depression (*incisura costalis I*) for the first costal cartilage, and below by a small facet, which, with a

FIG. 122.—Anterior (ventral) surface of sternum and costal cartilages.

FIG. 123.—Posterior (dorsal) surface of sternum.

similar facet on the upper angle of the middle portion of the bone, forms a notch (*incisura costalis II*) for the reception of the costal cartilage of the second rib. These articular surfaces are separated by a narrow, curved edge, which slopes from above downward and inward.

Second Piece.—The second piece, or *gladiolus*, considerably longer, narrower, and thinner than the first piece, is broader below than above.

Surfaces.—Its *anterior surface* (*planum sternale*) is nearly flat, directed upward and forward, and marked by three transverse lines which cross the bone opposite the third, fourth, and fifth articular depressions. These lines are produced by the union of the four separate pieces of which this part of the bone consists at an early period of life. At the junction of the third and fourth pieces is occasionally seen an orifice, the *sternal foramen*; it varies in size and form in different individuals and pierces the bone from before backward. This surface affords attachment on each side to the sternal origin of the *Pectoralis major*. The *posterior surface*, slightly concave, is also marked by three transverse lines, but they are less distinct than those in front; this surface affords attachment below, on each side, to the *Triangularis sterni* muscle, and occasionally presents the posterior opening of the sternal foramen.

Borders.—The *superior border* presents an oval surface for articulation with the manubrium. The *inferior border* is narrow, and articulates with the ensiform appendix. Each *lateral border* presents, at each superior angle, a small facet, which, with a similar facet on the manubrium, forms a cavity for the cartilage of the second rib; the four succeeding angular depressions receive the cartilages of the third, fourth, fifth, and sixth ribs; while each inferior angle presents a small facet, which, with a corresponding one on the ensiform appendix, forms a notch for the cartilage of the seventh rib. These articular depressions are known as *incisurae costales*. They are separated by a series of curved interarticular intervals, which diminish in length from above downward, and correspond to the intercostal spaces. Most of the cartilages belonging to the true ribs, as will be seen from the foregoing description, articulate with the sternum at the line of junction of two of its primitive component segments. This is well seen in many of the lower animals, where the separate parts of the bone remain ununited longer than in man. In this respect a striking analogy exists between the mode of connection of the ribs with the vertebral column and the connection of the costal cartilages with the sternum.

Third Piece.—The third piece, the *ensiform* or *xiphoid appendix*, is the smallest of the three; it is thin and elongated in form, cartilaginous in structure in youth, but more or less ossified at the upper part in the adult.

Surfaces.—Its *anterior surface* affords attachment to the chondroxiphoid ligament; its *posterior surface*, to some of the fibres of the *Diaphragm* and *Triangularis sterni* muscles; its *lateral borders*, to the aponeurosis of the abdominal muscles. Above it articulates with the lower end of the *gladiolus*, and at each superior angle presents a facet (*incisura costalis VII*), for the lower half of the cartilage of the seventh rib; below, by its pointed extremity, it gives attachment to the *linea alba*. This portion of the sternum varies much in appearance, being sometimes pointed, broad, and thin, sometimes bifid or perforated by a circular opening, occasionally curved or deflected considerably to one or the other side.

Structure.—The bone is composed of delicate cancellous structure, covered by a thin layer of compact tissue, which is thickest in the manubrium between the articular facets for the clavicles.

Development.—The cartilaginous sternum originally consists of two bars, situated one on either side of the mesal plane and connected with the rib cartilages of its own side. It is usual for the eighth cartilage to lose its attachment to the sternum and become attached to the seventh cartilage. The sternal end of the ninth cartilage divides longitudinally, the mesal part remains

attached to the sternum and becomes the ensiform process. The remaining part acquires attachment to the eighth cartilage. These two bars fuse with each other along the middle line, and the bone, including the ensiform appendix, is usually developed from *six* centres, one for the first piece or manubrium, four for the second piece or gladiolus, and one for the ensiform appendix.

FIG. 124.—Showing ventral ends of the upper seven (cartilaginous) ribs fused to form a pair of longitudinal sternal bars. (Rauber-Kopsch.)

Up to the middle of fetal life the sternum is entirely cartilaginous, and when ossification takes place the ossific granules are deposited in the middle of the intervals between the articular depressions for the costal cartilages, in the following order (Fig. 125): In the manubrium and first piece of the gladiolus, during the sixth month; in the second and third pieces of the gladiolus between the seventh and ninth months; the fourth piece of the gladiolus ossifies toward the latter part of the first year; the ensiform process ossifies between the fifth and eighteenth years. The centres appear in the upper part of each segment and proceed gradually downward. To these may be added the occasional existence, as described by Breschet, of two episternal centres, which make their appearance one on each side of the presternal notch. They are probably vestiges of the episternal bone of the monotremata and lizards. It occasionally happens that some of the segments are formed from more than

none centre, the number and position of which vary (Fig. 127). Thus, the first piece may have two, three, or even six centres. When two are present, they are generally situated one above the other, the upper one being the larger; the second piece has seldom more than one; the

FIG. 125.—Development of the sternum from six centres. Time of appearance.

FIG. 127.—Peculiarities in number of centres of sternum.

FIG. 128.—Peculiarities in mode of union of sternum.

¹ Sir George Humphry states that this is "probably the more complete condition."

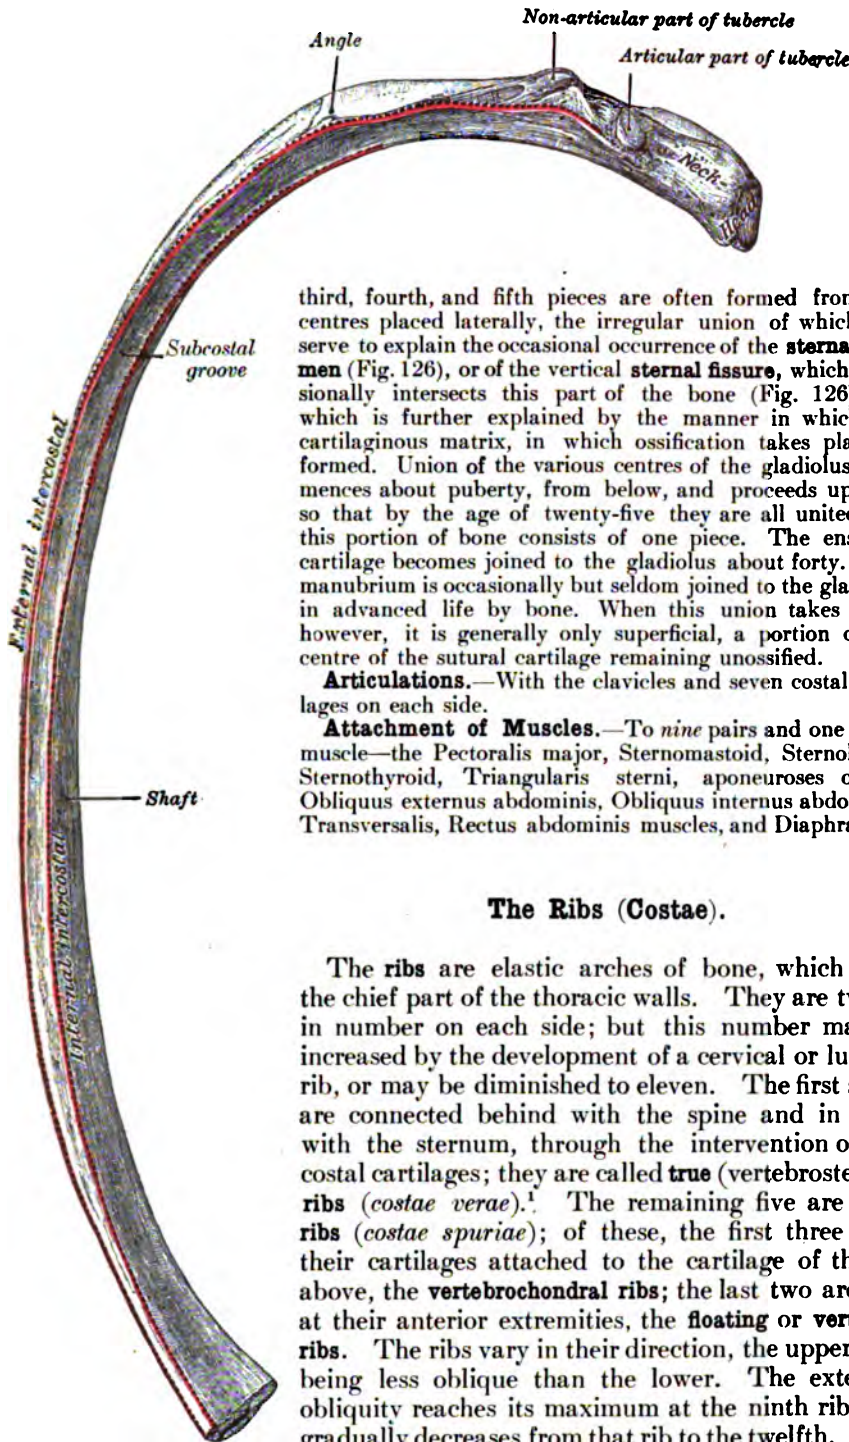

FIG. 129.—A central rib of the left side. Inferior aspect.

third, fourth, and fifth pieces are often formed from two centres placed laterally, the irregular union of which will serve to explain the occasional occurrence of the **sternal foramen** (Fig. 126), or of the vertical **sternal fissure**, which occasionally intersects this part of the bone (Fig. 126), and which is further explained by the manner in which the cartilaginous matrix, in which ossification takes place, is formed. Union of the various centres of the gladiolus commences about puberty, from below, and proceeds upward, so that by the age of twenty-five they are all united, and this portion of bone consists of one piece. The ensiform cartilage becomes joined to the gladiolus about forty. The manubrium is occasionally but seldom joined to the gladiolus in advanced life by bone. When this union takes place, however, it is generally only superficial, a portion of the centre of the sutural cartilage remaining unossified.

Articulations.—With the clavicles and seven costal cartilages on each side.

Attachment of Muscles.—To nine pairs and one single muscle—the Pectoralis major, Sternomastoid, Sternohyoid, Sternothyroid, Triangularis sterni, aponeuroses of the Obliquus externus abdominis, Obliquus internus abdominis, Transversalis, Rectus abdominis muscles, and Diaphragm.

The Ribs (Costae).

The **ribs** are elastic arches of bone, which form the chief part of the thoracic walls. They are twelve in number on each side; but this number may be increased by the development of a cervical or lumbar rib, or may be diminished to eleven. The first seven are connected behind with the spine and in front with the sternum, through the intervention of the costal cartilages; they are called **true** (vertebrosternal) **ribs** (*costae verae*).¹ The remaining five are **false ribs** (*costae spuriae*); of these, the first three have their cartilages attached to the cartilage of the rib above, the **vertebrochondral ribs**; the last two are free at their anterior extremities, the **floating** or **vertebral ribs**. The ribs vary in their direction, the upper ones being less oblique than the lower. The extent of obliquity reaches its maximum at the ninth rib, and gradually decreases from that rib to the twelfth. The ribs are situated one below the other in such a manner that spaces are left between them. Each

¹ Sometimes the eighth rib cartilage articulates with the sternum; this condition occurs more frequently on the right than on the left side.

space is called an **intercostal space** (*spatium intercostale*). The length of these spaces corresponds to the length of the ribs and their cartilages; their breadth is greater in front than behind, and between the upper than between the lower ribs. The ribs increase in length from the first to the seventh, when they again diminish to the twelfth. In breadth they decrease from above downward; in the upper ten the greatest breadth is at the sternal extremity.

Common Characters of the Ribs.—A rib from the middle of the series should be taken in order to study the common characters of the ribs (Figs. 129 and 130). Each rib presents two extremities, a **posterior or vertebral**, an **anterior or sternal**, and an intervening portion—the **body or shaft**.

Posterior Extremity.—The **posterior or vertebral extremity** presents for examination a head, neck, and tuberosity.

The **head** (*capitulum costae*) (Fig. 130) is marked by a kidney-shaped articular surface, divided by a horizontal ridge (*crista capiti*) into two facets for

FIG. 130.—A central rib of the left side, viewed from behind.

articulation with the costal cavity formed by the junction of the bodies of two contiguous thoracic vertebræ; the upper facet is small, the inferior one of larger size; the ridge separating them serves for the attachment of the interarticular ligament.

The **neck** (*collum costae*) is that flattened portion of the rib which extends outward from the head; it is about an inch long, and is placed in front of the transverse process of the lower of the two vertebræ with which the head articulates. Its **anterior surface** is flat and smooth, its **posterior surface** is rough for the attachment of the middle costotransverse ligament, and is perforated by numerous foramina, the direction of which is less constant than those found on the inner surface of the shaft. Of its two borders, the **superior border** presents a rough **crest** (*crista colli costae*) for the attachment of the anterior costotransverse ligament; its **inferior border** is rounded. On the posterior surface of the neck, just where it joins the shaft, and nearer the lower than the upper border, is an eminence—the **tuberosity**, or **tubercle**.

The **tuberosity** (*tuberculum costae*) consists of an articular and a nonarticular portion. The **articular portion** (*facies articularis tuberculi costae*), the more internal and inferior of the two, presents a small, oval surface or articulation with the extremity of the transverse process of the lower of the two vertebræ to which the head is connected. The **nonarticular portion** is a rough elevation, which

affords attachment to the posterior costotransverse ligament. The tubercle is much more prominent in the upper than in the lower ribs.

Anterior Extremity.—The **anterior** or **sternal extremity** is flattened, and presents a porous, oval, concave depression, into which the costal cartilage is received.

The **shaft** (*corpus costae*) is thin and flat, so as to present two surfaces, an external and an internal, and two borders, a superior and an inferior.

The **external surface** is convex, smooth, and marked at its back part, a little in front of the tuberosity, by a prominent line, directed obliquely from above downward and outward; this gives attachment to a tendon of the Iliocostalis muscle or of one of its accessory portions, and is called the **angle** (*angulus costae*). At this point the rib is bent in two directions. If the rib is laid upon its lower border, it will be seen that the portion of the shaft in front of the angle rests upon this border, while the portion of the shaft behind the angle is bent inward and at the same time tilted upward. The interval between the angle and the tuberosity increases gradually from the second to the tenth rib. The portion of bone between these two parts is rounded, rough, and irregular, and serves for the attachment of the Longissimus dorsi muscle. The portion of bone between the tubercle and sternal extremity is also slightly twisted upon its own axis, the external surface looking downward behind the angle, a little upward in front of it. This surface presents toward its sternal extremity an oblique line, the **anterior angle**.

The **internal surface** is concave, smooth, directed a little upward behind the angle, a little downward in front of it. This surface is marked by a ridge which commences at the lower extremity of the head; it is strongly marked as far as the inner side of the angle, and gradually becomes lost at the junction of the anterior with the middle third of the bone. The interval between it and the inferior border presents a groove, **subcostal groove** (*sulcus costae*), for the intercostal vessels and nerve. At the back part of the bone this groove belongs to the inferior border, but just in front of the angle, where it is deepest and broadest, it corresponds to the internal surface. The superior edge of the groove is rounded; it serves for the attachment of the Internal intercostal muscle. The inferior edge corresponds to the lower margin of the rib and gives attachment to the External intercostal muscle. Within the groove are seen the orifices of numerous small foramina which traverse the wall of the shaft obliquely from before backward.

The **superior border**, thick and rounded, is marked by an external and an internal lip, more distinct behind than in front; they serve for the attachment of the External and Internal intercostal muscles.

The **inferior border**, thin and sharp, has attached to it the External intercostal muscle.

Peculiar Ribs.—The ribs which require especial consideration are five in number, viz., the **first**, **second**, **tenth**, **eleventh**, and **twelfth**.

First Rib.—The first rib (Fig. 131) is the shortest and the most curved of all the ribs; it is broad and flat, its surfaces looking upward and downward, and its borders inward and outward. The **head** is of small size, rounded, and presents only a single articular facet for articulation with the body of the first thoracic vertebra. The **neck** is narrow and rounded. The **tuberosity**, thick and prominent, rests on the outer border. There is *no angle*, but in this situation the rib is slightly bent, with the convexity of the bend upward, so that the head of the bone is directed downward. The **upper surface** of the shaft is marked by two shallow depressions, separated by a small rough surface (*tuberculum scaleni*) for the attachment of the Scalenus anticus muscle—the shallow groove in front of it transmitting the subclavian vein, the deeper groove behind it (*sulcus subclaviae*) the subclavian artery. Between the groove for the subclavian artery and the tuberosity is a rough surface, for the attachment of the Scalenus medius muscle. The **under surface** is smooth, and destitute of the groove observed on the other

ribs. The **outer border** is convex, thick, and rounded, and at its posterior part gives attachment to the first serration of the Serratus magnus; the **inner** is concave, thin, and sharp, and marked about its centre by the commencement of

FIG. 133

FIG. 134

FIG. 135

FIGS. 131 to 135.—Peculiar ribs.

the rough surface for the Scalenus anticus. The **anterior extremity** is larger and thicker than any of the other ribs.

Second Rib.—The second rib (Fig. 132) is much longer than the first, but bears a very considerable resemblance to it in the direction of its curvature. The non-

articular portion of the tuberosity is occasionally only slightly marked. The **angle** is slight and situated close to the tuberosity, and the **shaft** is not twisted, so that both ends touch any plane surface upon which it may be laid; but there is a similar though slighter bend, with its convexity upward, to that found in the first rib. The shaft is not horizontal, like that of the first rib, its **outer surface**, which is convex, looking upward and a little outward. It presents, near the middle, a rough eminence (*tuberositas costae II*), for the attachment of part of the first and all of the second digitations of the Serratus magnus; behind and above which is attached the Scalenus posticus. The **inner surface**, smooth and concave, is directed downward and a little inward; it presents a short groove toward its posterior part.

Tenth Rib.—The tenth rib (Fig 133) has only a single articular facet on its head.

Eleventh and Twelfth Ribs.—The eleventh and twelfth ribs (Figs. 134 and 135) have each a single articular facet on the head, which is of rather large size; they have *no neck or tuberosity*, and are pointed at the extremity. The eleventh has a slight angle and a shallow groove on the lower border. The twelfth has neither, and is much shorter than the eleventh, and the head has a slight inclination downward. Sometimes the twelfth rib is even shorter than the first.

Structure.—The ribs consist of cancellous tissue enclosed in a thin layer of compact bone.

Development.—Each rib, with the exception of the last two, is developed from *three* centres, *one* for the shaft near the angle, *one* for the head, and *one* for the tubercle. The last two ribs have only two centres, that for the tubercle being wanting. Ossification commences in the shaft of the ribs between the ninth and eleventh weeks before its appearance in the vertebrae. The epiphysis of the head, which is of slightly angular shape, and that for the tubercle, of a lenticular form, make their appearance between the sixteenth and twentieth years, and are not united to the rest of the bone until about the twenty-fifth year.

Attachment of Muscles.—To *nineteen*—the Intercostales externi et interni, Scalenus anticus, Scalenus medius, Scalenus posticus, Pectoralis minor, Serratus magnus, Obliquus externus abdominis, Quadratus lumborum, Diaphragm, Latissimus dorsi, Serratus posticus superior, Serratus posticus inferior, Iliocostalis, Musculus accessorius ad iliocostalem, Longissimus dorsi, Cervicalis ascendens, Levatores costarum, and Infracostales.

The Costal Cartilages.

The **costal cartilage** (*cartilago costalis*) (Fig. 122) is white, hyaline cartilage. The cartilages serve to prolong the ribs forward to the front of the thorax, and they contribute very materially to the elasticity of its walls. The first seven are connected with the sternum, the next three with the lower border of the cartilage of the preceding rib. The cartilages of the last two ribs have pointed extremities, which terminate in free ends in the walls of the abdomen. Like the ribs, the costal cartilages vary in their length, breadth, and direction. They increase in length from the first to the seventh, then gradually diminish to the last. They diminish in breadth, as well as the intervals between them, from the first to the last. They are broad at their attachment to the ribs, and taper toward their sternal extremities, excepting the first two, which are of the same breadth throughout, and the sixth, seventh, and eighth, which are enlarged where their margins are in contact. In direction they also vary; the first descends a little, the second is horizontal, the third ascends slightly, while all the rest follow the course of the ribs for a short extent, and then ascend to the sternum or preceding cartilage. Each costal cartilage presents two surfaces, two borders, and two extremities.

Surfaces.—The **anterior surface** is convex, and looks forward and upward; that of the first gives attachment to the costoclavicular ligament and the Subclavius muscle; that of the second, third, fourth, fifth, and sixth, at their sternal ends, to the Pectoralis major.¹ The others are covered by, and give partial attachment to, some of the great flat muscles of the abdomen. The **posterior surface** is con-

¹ The first and seventh also, occasionally, give origin to the same muscle.

cave, and directed backward and downward, the first giving attachment to the Sternothyroid, the third to the sixth inclusive to the *Triangularis sterni*, and the six or seven inferior ones to the *Transversalis* muscle and the Diaphragm.

Borders.—Of the two borders, the **superior border** is concave, the **inferior** convex; they afford attachment to the Internal intercostal muscles, the upper border of the sixth giving attachment to the *Pectoralis major* muscle. The contiguous borders of the sixth, seventh, and eighth, and sometimes the ninth and tenth, costal cartilages present small, smooth, oblong-shaped facets at the points where they articulate.

Extremities.—Of the two extremities, the **outer extremity** is continuous with the osseous tissue of the rib to which it belongs. The **inner extremity** of the first is continuous with the sternum; the six succeeding ones have rounded extremities, which are received into shallow concavities on the lateral margins of the sternum. The inner extremities of the eighth, ninth, and tenth costal cartilages are pointed, and are connected with the cartilage above. Those of the eleventh and twelfth are free and pointed.

The costal cartilages are most elastic in youth, those of the false ribs being more so than the true. In old age they become of a deep yellow color, and are prone to calcify.

Attachment of Muscles.—To *nine*—the *Subclavius*, *Sternothyroid*, *Pectoralis major*, *Internal oblique*, *Transversalis*, *Rectus abdominis*, *Diaphragm*, *Triangularis sterni*, and *Internal intercostals*.

Surface Form.—The bones of the thorax are to a very considerable extent covered by muscles, so that in the strongly developed muscular subject they are for the most part concealed. In the emaciated subject, on the other hand, the ribs, especially in the lower and lateral region, stand out as prominent ridges with the sunken, intercostal spaces between them.

In the median line, in front, the superficial surface of the sternum is to be felt throughout its entire length, at the bottom of a deep median furrow (the **sternal furrow**) situated between the two great pectoral muscles. These muscles overlap the anterior surface somewhat, so that the whole of the sternum in its entire width is not subcutaneous; and this overlapping is greater opposite the centre of the bone than above and below, so that the furrow is wider at its upper and lower parts, but narrower in the middle. The centre of the upper border of the sternum is visible, constituting the **presternal notch**, but the lateral parts of this border are obscured by the tendinous origins of the *Sternomastoid* muscles, which present themselves as oblique tendinous cords, which narrow and deepen the notch. Lower down on the subcutaneous surface, a well-defined transverse ridge, the **angulus Ludovici**, is always to be felt. This denotes the line of junction of the manubrium and the body of the bone, and is a useful guide to the second costal cartilage, and thus to the identity of any given rib. The second rib being found through its costal cartilage, it is easy to count downward and find any other. From the middle of the sternum the furrow spreads out, and, exposing more of the surface of the body of the bone, terminates below in a sudden depression, the **infrasternal depression**, or **pit of the stomach** (*scrobiculus cordis*), which corresponds to the ensiform cartilage. This depression lies between the cartilages of the seventh ribs, and in it the ensiform cartilage may be felt. The sternum in its vertical diameter presents a general convexity forward, the most prominent point of which is at the joint between the manubrium and gladiolus.

On each side of the sternum the costal cartilages and ribs on the front of the thorax are partially obscured by the great pectoral muscles, through which, however, they are to be felt as ridges, with yielding intervals between them, corresponding to the intercostal spaces. Of these spaces, the one between the second and third ribs is the widest, the next two somewhat narrower, and the remainder, with the exception of the last two, comparatively narrow.

The lower border of the *Pectoralis major* muscle corresponds to the fifth rib, and below this, on the front of the thorax, the broad, flat outline of the ribs, as they begin to ascend, and the more rounded outline of the costal cartilages, are often visible. The lower boundary of the front of the thorax, the **abdominothoracic arch**, which is most plainly seen by arching the body backward, is formed by the ensiform cartilage and the cartilages of the seventh, eighth, ninth, and tenth ribs, and the extremities of the eleventh and twelfth ribs or their cartilages.

On each side of the thorax, from the axilla downward, the flattened external surfaces of the ribs may be defined in the form of oblique ridges, separated by depressions corresponding to the intercostal spaces. They are, however, covered by muscles, which obscure their outline to a certain extent in the strongly developed. Nevertheless, the ribs, with the exception of the first, can generally be followed over the front and sides of the thorax without difficulty. The first rib, being almost completely covered by the clavicle and scapula, can only be distinguished in a

small portion of its extent. At the back the angles of the ribs form a slightly marked oblique line on each side of and some distance from the vertebral spines. This line diverges somewhat as it descends, and external to it is a broad, convex surface caused by the projection of the ribs beyond their angles. Over this surface, except where covered by the scapula, the individual ribs can be distinguished.

Applied Anatomy.—*Malformations of the sternum* present nothing of surgical importance beyond the fact that abscesses of the mediastinum may sometimes escape through the sternal foramen. *Fractures of the sternum* are by no means common, due, no doubt, to the elasticity of the ribs and their cartilages, which support it like so many springs. When broken it is frequently associated with fracture of the vertebral column, and may be caused by forcibly bending the body either backward or forward until the chin becomes impacted against the top of the sternum. It may also be fractured by direct violence or by muscular action. The fracture usually occurs in the upper half of the body of the bone. *Dislocation of the gladiolus from the manubrium* also takes place, and is sometimes described as a fracture.

The bone, cancellous in structure and being subcutaneous, is frequently the seat of *gummatous tumors*, and not uncommonly is affected with *caries*. Occasionally the bone, and especially its ensiform appendix, becomes altered in shape and driven inward, in workmen, by the pressure of tools against the chest.

The ribs are frequently broken, though from their connections and shape they are able to withstand great force, yielding under the injury and recovering themselves like a spring. The middle of the series are the ones most liable to fracture. The first, and to a less extent the second, being protected by the clavicle, are rarely fractured; and the eleventh and twelfth, on account of their loose and floating condition, enjoy a like immunity. The fracture generally occurs from indirect violence, from forcible compression of the thoracic wall, and the bone then gives way at its weakest part—i. e., just in front of the angle. But the ribs may also be broken by direct violence, when the bone gives way and is driven inward at the point struck, or they may be broken by muscular action. It seems probable, however, that in the latter case the bone has undergone some atrophic changes. Fracture of the ribs is frequently complicated by some injury to the viscera contained within the thorax or upper part of the abdominal cavity, and this is most likely to occur in fractures from direct violence. Occasionally supernumerary ribs exist. They may come from the lumbar vertebræ or from the cervical vertebræ. A lumbar rib does not cause discomfort.¹ A *cervical rib* is due to excessive development of the costal element of the seventh cervical vertebra. In nearly two-thirds of the reported cases the condition is bilateral. It rarely produces symptoms until after the twentieth year. The symptoms are a superficial pulsation of the subclavian artery, a prominence which can be felt, and evidences of pressure in the brachial plexus (Carl Beck). Beck divides the different types of the condition as follows: "(a) Slight degree: The cervical rib reaches beyond the transverse process. (b) More advanced: The cervical rib reaches beyond the transverse process, either with a free end or touching the first rib. (c) Almost complete: The connection between the cartilage of the first rib is formed either by means of a distinct band or by the end of its long body. (d) Complete: It has become a true rib and possesses a true cartilage which unites with the cartilage of the first rib."² A very rare condition is a rib from the sixth cervical vertebra. The diagnosis is confirmed by the x-rays. The treatment of cervical rib is excision.

Fracture of the costal cartilages may also take place, though it is a comparatively rare injury.

The thorax is frequently found to be altered in shape in certain diseases. The shape of the thorax in those suffering from rhachitis is produced chiefly by atmospheric pressure. The balance between the air on the inside of the thorax and the air on the outside during some stage of respiration is not equal, the preponderance being in favor of the air outside; and this, acting on the softened ribs, causes them to be forced in at the junction of the cartilages with the bones, which is the weakest part. In consequence of this the sternum projects forward with a deep depression on either side caused by the sinking in of the softened ribs. The depression is less on the left side, on account of the ribs being supported by the heart. The condition is known as *pigeon-breast*. The lower ribs, however, are not involved in this deformity, as they are prevented from falling in by the presence of the stomach, liver, and spleen. And when the liver and spleen are enlarged, as they sometimes are in rhachitis, the lower ribs may be pushed outward; this causes a transverse constriction just above the costal arch. The anterior extremities of the ribs are usually enlarged in rhachitis, giving rise to what has been termed the *rhachitic rosary*. The *phthisical chest* is often long and narrow, flattened from before backward, and with great obliquity of the ribs and projection of the scapulæ. In *pulmonary emphysema* the thorax is enlarged in all its diameters, and presents on section an almost circular outline. It has received the name of the *barrel-shaped chest*. In severe cases of *lateral curvature of the spine* the thorax becomes much distorted. In consequence of the rotation of the bodies of the vertebræ which takes place in this disease the ribs opposite the convexity of the thoracic curve become extremely convex behind, being thrown out and bulging, and at the same time flattened

¹ Carl Beck, in Jour. Amer. Med. Assoc., June 17, 1905.

² Jour. Amer. Med. Assoc., June 17, 1905.

in front, so that the two bends of the same rib are almost parallel. Coincident with this, the ribs on the opposite side, on the concavity of the curve, are sunken and depressed behind and bulging and convex in front. In addition to this the ribs become occasionally welded together by bony material.

The ribs are frequently the seat of *caries* leading to abscesses and sinuses, which may burrow to a considerable extent over the wall of the thorax. The only special anatomical point in connection with abscesses and sinuses is that care must be taken in dealing with them that the intercostal space is not punctured and the pleural cavity opened or the intercostal vessels wounded, as the necrosed portion of bone is generally situated on the internal surface of the rib.

In cases of *empyema* the thorax requires opening to evacuate the pus. There is considerable difference of opinion as to the best position to do this. Probably the best place for intercostal drainage is between the fifth and sixth ribs, in or a little in front of the mid-axillary line. This is the last part of the cavity to be closed by the expansion of the lung; it is not thickly covered by soft parts; the space between the two ribs is sufficiently great to allow of the introduction of a fair-sized drainage tube, and when the patient is confined to bed he does not lie upon the drainage tube as he does when the opening is posterior. Better than intercostal drainage in the vast majority of cases is rib resection and drainage. A portion of the fifth or sixth rib should be removed in the mid-axillary line. In *chronic empyema* the lung becomes shrunken and adherent, and simple drainage will not bring about a cure. It is necessary in such cases to do an operation that will permit of collapse of the chest wall. *Estlander's operation* consists in resecting a portion of every rib which overlies the cavity of the empyema. *Schede's operation* consists in removing ribs from the second rib down over the empyema cavity. The ribs are removed from cartilages to angles, and intercostal muscles and the parietal layer of the pleura are also taken away. Fowler and de Lorme not only practise extensive rib resection and remove the parietal layer of the pleura, but also remove pulmonary pleura (*total pleurectomy* or *pulmonary decortication*).

THE EXTREMITIES.

The **extremities**, or **limbs**, are those long, jointed appendages of the body which are connected to the trunk by one end and free in the rest of their extent. They are *four* in number: an **upper** or **thoracic pair**, connected with the thorax through the intervention of the shoulder and subservient mainly to prehension; and a **lower** or **pelvic pair**, connected with the pelvis, intended for support and locomotion. Both pairs of limbs are constructed after one common type, so that they present numerous analogies, while at the same time certain differences are observed between the upper and lower pair, dependent on the peculiar offices they have to perform.

The bones by which the upper and lower limbs are attached to the trunk are named, respectively, the **shoulder** and **pelvic girdles**, and they are constructed on the same general type, though presenting certain modifications relating to the different uses to which the upper and lower limbs are respectively applied. The **shoulder girdle** is formed by the scapulæ and clavicles, and is imperfect in front and behind. In front, however, the girdle is completed by the upper end of the sternum, with which the inner extremities of the clavicle articulate. Behind, the girdle is widely imperfect and the scapula is connected to the trunk by muscles only. The **pelvic girdle** is formed by the innominate bones, and is completed in front through the symphysis pubis, at which the two innominate bones articulate with each other. It is imperfect behind, but the intervening gap is filled in by the upper part of the sacrum. The pelvic circle, therefore, presents, with the sacrum, a complete ring, massive and comparatively rigid, in marked contrast to the lightness and mobility of the shoulder girdle.

THE UPPER EXTREMITY.

The bones of the upper extremity consist of the clavicle and scapula (*pectoral girdle*), the humerus (*arm*), the radius and ulna (*forearm*), the carpal bones (*wrist*), the metatarsal bones (*palm*), and the phalanges (*digits*).

THE SHOULDER GIRDLE.

The shoulder girdle consists of the **clavicle** and the **scapula**.

The Clavicle, or Collar Bone (*Clavicula*).

The **clavicle** forms the anterior portion of the shoulder girdle. It is a long bone, curved somewhat like the italic letter *f*, and placed nearly horizontally at the upper and anterior part of the thorax, immediately over the first rib. It articulates by its inner extremity with the upper border of the sternum, and by its outer extremity with the acromion process of the scapula, serving to sustain the upper extremity in the various positions which it assumes, while at the same time it allows of great latitude of motion in the arm.¹ It presents a double curvature when looked at in front, the convexity being forward at the sternal end and the concavity at the scapular end. Its outer third is flattened from above downward, and extends, in the natural position of the bone, from a point opposite the coracoid process to the acromion. Its inner two-thirds are of a prismatic form, and extend from the sternum to a point opposite the coracoid process of the scapula.

Outer or Flattened Portion.—The **outer third** is flattened from above downward, so as to present two surfaces, an upper and a lower; and two borders, an anterior and a posterior.

Surfaces.—The **upper surface** is flat, rough, marked by impressions for the attachment of the Deltoid in front and the Trapezius behind; between these two impressions a small portion of the bone is subcutaneous. The **under surface** is flattened. At its posterior border, a little external to the point where the prismatic joins with the flattened portion, is a rough eminence, the **conoid tubercle** (*tuberositas coracoidea*); this, in the natural position of the bone, surmounts the coracoid process of the scapula and gives attachment to the conoid ligament. From this tubercle an oblique line, occasionally a depression, passes forward and outward to near the outer end of the anterior border; it is called the **oblique line** or **trapezoid ridge**, and affords attachment to the trapezoid ligament.

Borders.—The **anterior border** is concave, thin, and rough, and gives attachment to the Deltoid; it occasionally presents, at its inner end, at the commencement of the deltoid impression, a tubercle, the **deltoid tubercle**. The **posterior border** is convex, rough, broader than the anterior, and gives attachment to the Trapezius.

Inner or Prismatic Portion.—The prismatic portion forms the **inner two-thirds** of the bone. It is curved so as to be convex in front, concave behind, and is marked by three borders, separating three surfaces.

Borders.—The **anterior border** is continuous with the anterior margin of the flat portion, and separates the anterior surface from the posterior; at the inner half of the clavicle it forms the lower boundary of an elliptical space for the attachment of the clavicular portion of the Pectoralis major, and approaches the posterior border of the bone; it coincides with the anterior margin of the subclavian groove. The **superior border** is continuous with the posterior margin of the flat portion, and separates the anterior from the posterior surface. At its commencement it is smooth and rounded, becomes rough toward the inner third for the attachment of the Sternomastoid muscle, and terminates at the upper angle of the sternal extremity. The **posterior or subclavian border** separates the posterior

¹ The clavicle acts especially as a fulcrum to enable the muscles to give lateral motion to the arm. It is accordingly absent in those animals in which the fore limbs are used only for progression, but is present for the most part in those animals in which the anterior extremities are clawed and used for prehension, though in some of them—as, for instance, in a large number of the carnivora—it is merely a rudimentary bone suspended among the muscles, and not articulating with the scapula or sternum.

from the inferior surface, and extends from the conoid tubercle to the rhomboid impression. It forms the posterior boundary of the groove for the Subclavius muscle, and gives attachment to a layer of cervical fascia covering the Omohyoid muscle.

Surfaces.—The **anterior surface** is included between the superior and anterior borders. It is directed forward and a little upward at the sternal end, outward and still more upward at the acromial extremity, where it becomes continuous with the upper surface of the flat portion. Externally, it is smooth, convex, nearly subcutaneous, being covered only by the Platysma; but, corresponding to the inner half of the bone, it is divided by a more or less prominent line into two parts—a lower portion, elliptical in form, rough, and slightly convex, for the attachment of the Pectoralis major; and an upper part, which is rough, for the attachment of the Sternomastoid. Between the two muscular impressions

FIG. 136.—Left clavicle. Superior surface.

FIG. 137.—Left clavicle. Inferior surface.

is a small subcutaneous interval. The **posterior or cervical surface** is smooth, flat, and looks backward toward the root of the neck. It is limited, *above*, by the superior border; *below*, by the posterior border; *internally*, by the margin of the sternal extremity; *externally*, it is continuous with the posterior border of the flat portion. It is concave from within outward, and is in relation, by its lower part, with the suprascapular vessels. This surface, at about the junction of the inner and outer curves, is also in close relation with the brachial plexus and subclavian vessels. It gives attachment, near the sternal extremity, to part of the Sternohyoid muscle; and presents, at or near the middle, a foramen, **nutrient foramen**. It opens into a canal, **nutrient canal**, which is directed obliquely outward and transmits the chief nutrient artery of the bone. Sometimes there are two foramina on the posterior surface, or one on the posterior and one on the inferior surface. The **inferior or subclavian surface** is bounded; in *front*, by the anterior border;

behind, by the posterior border. It is narrow internally, but gradually increases in width externally, and is continuous with the under surface of the flat portion. Commencing at the sternal extremity may be seen a small facet, the **costal facet**, for articulation with the cartilage of the first rib. This is continuous with the articular surface at the sternal end of the bone. External to this is a broad, rough surface, the **rhomboid impression** (*tuberositas costalis*), rather more than an inch in length, for the attachment of the costoclavicular (rhomboid) ligament. The remaining part of this surface is occupied by a longitudinal groove, the **subclavian groove**, broad and smooth externally, narrow and more uneven internally; it gives attachment to the Subclavius muscle, and by its margins to the costocoracoid membrane, which splits to enclose the muscle. Not infrequently this groove is subdivided into two parts by a longitudinal line, which gives attachment to the intermuscular septum of the Subclavius muscle.

Internal or Sternal Extremity (*extremitas sternalis*).—The internal or sternal extremity of the clavicle is triangular in form, directed inward and a little downward and forward; and presents an **articular facet** (*facies articularis sternalis*), concave from before backward, convex from above downward, which articulates with the sternum through the intervention of an intra-articular fibrocartilage; the circumference of the articular surface is rough, for the attachment of numerous ligaments. The **posterior border** of this surface is prolonged backward, so as to increase the size of the articular facet; the **upper border** gives attachment to the intra-articular fibrocartilage, and the **lower border** is continuous with the costal facet on the inner end of the inferior surface, which articulates with the cartilage of the first rib.

Outer or Acromial Extremity (*extremitas acromialis*).—The outer or acromial extremity, directed outward and forward, presents a small, flattened, oval facet, **acromial surface** (*facies articularis acromialis*), which looks obliquely downward, and which articulates with the acromion process of the scapula. The circumference of the articular facet is rough, especially above, for the attachment of the acromioclavicular ligaments.

Peculiarities of the Bone in the Sexes and in Individuals.—In the female the clavicle is generally shorter, thinner, less curved, and smoother than in the male; in the female it is placed almost, if not quite, horizontal, while in the male it inclines slightly downward and inward. In those persons who perform considerable manual labor, which brings into constant action the muscles connected with this bone, it becomes thicker and more curved, its ridges for muscle attachment become prominently marked. The right clavicle is generally longer, thicker, and rougher than the left.

Structure.—The shaft, as well as the extremities, consists of cancellous tissue, invested by a compact layer much thicker in the middle than at either end. It has no true medullary cavity.

Development.—From *two* centres, one for the shaft and outer extremity and one for the sternal extremity. The primary centre for the shaft appears very early, before that of any other bone, at about the fifth or sixth week of fetal life. The secondary centre for the sternal end makes its appearance about the fifteenth to the twentieth year, and unites with the rest of the bone about the twenty-fifth year.

Articulations.—With the sternum, scapula, by intra-articular fibrocartilaginous disks, and with the cartilage of the first rib.

Attachment of Muscles.—To *six*—the Sternomastoid, Trapezius, Pectoralis major, Deltoid, Subclavius, and Sternohyoid.

Surface Form.—The clavicle can be felt throughout its entire length, even in persons who are very fat. Commencing at the inner end, the enlarged sternal extremity, where the bone projects above the upper margin of the sternum, can be felt, forming with the sternum and the rounded tendon of the Sternomastoid a V-shaped notch, the **presternal notch**. Passing outward, the shaft of the bone can be felt immediately under the skin, with its convexity forward in the inner two-thirds, the surface partially obscured above and below by the attachments of the Sternomastoid and Pectoralis major muscles. In the outer third it forms a gentle curve backward, and terminates at the outer end in a somewhat enlarged extremity which articulates with the acromion process of the scapula. The direction of the clavicle is almost, if not quite, horizontal when the arm is lying quietly by the side, though in well-developed subjects it may

incline a little upward at its outer end. Its direction is, however, very changeable, altering with the varying movements of the shoulder-joint.

Applied Anatomy.—The clavicle is the most frequently *fractured* of any single bone in the body. This is due to the fact that it is much exposed to violence, and is the only bony connection between the upper limb and the trunk. The bone, moreover, is slender, and is very superficial. The bone may be broken by direct or indirect violence or by muscular action. The most common cause is, however, from indirect violence, and the bone then gives way at the junction of the fixed outer one-third with the movable inner two-thirds of the bone. This is the weakest and most slender part of the bone. The fracture is generally oblique, and the displacement of the outer fragments is inward, away from the surface of the body; hence, compound fracture of the clavicle is of rare occurrence. The inner fragment, as a rule, is little displaced. Beneath the bone the main vessels of the upper limb and the great nerve cords of the brachial plexus lie on the first rib, and are liable to be wounded in fracture, especially in fracture from direct violence, when the force of the blow drives the broken ends inward. Fortunately, the Subclavius muscle is interposed between these structures and the clavicle, and this often protects them from injury.

The clavicle is not uncommonly the seat of *sarcomatous tumors*, rendering the operation of excision of the entire bone necessary. This operation is best performed by exposing the bone freely, disarticulating at the acromial end, and turning it inward. The removal of the outer part is comparatively easy, but resection of the inner part is fraught with difficulty, the main danger being the risk of wounding the great veins which are in relation with its under surface.

The Scapula, or Shoulder Blade.

The **scapula** forms the back part of the shoulder girdle. It is a large flat bone, triangular in shape, situated at the posterior aspect and side of the thorax, between the second and seventh or sometimes the eighth rib, its internal border or base being about an inch from and nearly but not quite parallel with the spinous processes of the vertebræ, so that it is rather closer to them above than below. It presents for examination two surfaces, three borders, and three angles.

Surfaces.—The **anterior or ventral surface** (*facies costalis*) (Fig. 138) presents a broad concavity, the **subscapular fossa** (*fossa subscapularis*). It is marked, in the inner two-thirds, by several **oblique ridges** (*lineæ musculares*), which pass outward and upward; the outer third is smooth. The oblique ridges give origin to the tendinous intersections, and the surfaces between them to the fleshy fibres, of the Subscapularis muscle. The outer third of the fossa is smooth, is covered by, but does not afford attachment to, the fibres of this muscle. This surface is separated from the internal border by a smooth, triangular margin at the superior and inferior angles, and in the interval between these by a narrow edge which is often deficient. This marginal surface affords attachment throughout its entire extent to the Serratus magnus muscle. The subscapular fossa presents a transverse depression at its upper part, where the bone appears to be bent on itself, forming a considerable angle, called the **subscapular angle** (*angulus subscapularis*), thus giving greater strength to the body of the bone from its arched form, while the summit of the arch serves to support the spine and acromion process. It is in this situation that the fossa is deepest, so that the thickest part of the Subscapularis muscle lies in a line perpendicular to the plane of the glenoid cavity, and must consequently operate most effectively on the head of the humerus, which is contained in that cavity.

The **posterior or dorsal surface** (*facies dorsalis*) (Fig. 139) is arched from above downward, alternately concave and convex from side to side. It is subdivided unequally into two parts by the **spine**; the portion above the spine is called the **supraspinous fossa**, and that below it the **infraspinous fossa**.

The **supraspinous fossa** (*fossa supraspinata*), the smaller of the two, is concave, smooth, and broader at the vertebral than at the humeral extremity. It affords attachment by its inner two-thirds to the Supraspinatus muscle.

The **infraspinous fossa** (*fossa infraspinata*) is much larger than the preceding;

toward its vertebral margin a shallow concavity is seen at its upper part; its centre presents a prominent convexity, while toward the axillary border is a deep groove which runs from the upper toward the lower part. The inner two-thirds of this surface affords origin to the *Infraspinatus* muscle; the outer third is only covered by it, without giving attachment to its fibres. This surface is separated from the axillary border by an elevated ridge, which runs from the lower margin of the glenoid

FIG. 138.—Left scapula. Anterior surface or venter.

cavity downward and backward to the internal border, about an inch above the inferior angle. The ridge serves for the attachment of a strong aponeurosis which separates the Infrapinatus from the two Teres muscles. The surface of bone between this line and the axillary border is narrow in the upper two-thirds of its extent, and traversed near its centre by a groove for the passage of the dorsalis scapulæ vessels; it affords origin to the Teres minor muscle. Its lower third

above downward, its apex corresponding to the vertebral border, its base (which is directed outward) to the neck of the scapula. It presents two surfaces and three borders. Its *superior surface* is concave, assists in forming the supraspinous fossa, and affords attachment to part of the Supraspinatus muscle. Its *inferior surface* forms part of the infraspinous fossa, gives origin to part of the Infraspinatus muscle, and presents near its centre the orifice of a nutrient canal. Of the three borders, the *anterior* is attached to the dorsum of the bone; the *posterior*, or *crest* of the spine, is broad, and presents two lips and an intervening rough interval. To the *superior lip* is attached the Trapezius to the extent shown in Fig. 139. A rough tubercle is generally seen occupying that portion of the spine which receives the insertion of the middle and inferior fibres of this muscle. From the *inferior lip*, throughout its whole length, arises the Deltoid. The interval between the lips is also partly covered by the tendinous fibres of these muscles. The *external border*, or *base*, the shortest of the three, is slightly concave, its edge thick and round, continuous above with the under surface of the acromion process, below with the neck of the scapula. The narrow portion of bone external to this border, and separating it from the glenoid cavity, is called the **great scapular notch**, and serves to connect the supra- and infraspinous fossæ.

The **acromion process** (*acromion*) is a large and somewhat triangular or oblong process, flattened from behind forward, directed at first a little outward, and then curving forward and upward, so as to overhang the glenoid cavity. Its *upper surface*, directed upward, backward, and outward, is convex, rough, and gives origin to some fibres of the Deltoid, and in the rest of its extent it is subcutaneous. Its *under surface* is smooth and concave. Its *outer border* is thick and irregular, and presents three or four tubercles for the tendinous origins of the Deltoid muscle. Its *inner margin*, shorter than the outer, is concave, gives attachment to a portion of the Trapezius muscle, and presents about its centre a small oval surface for articulation with the acromial end of the clavicle. Its *apex*, which corresponds to the point of meeting of these two borders in front, is thin, and has attached to it the coracoacromial ligament.

Margins, or Borders of the Scapula.—The *superior border* (*margo superior*) is the shortest and thinnest of the three borders; it is concave and extends from the internal angle to the coracoid process. At its outer part is a deep, semicircular notch, the **suprascapular notch** (*incisura scapulae*), formed partly by the base of the coracoid process. The notch is converted into a foramen by the suprascapular ligament, and serves for the passage of the suprascapular nerve. Sometimes this foramen is entirely surrounded by bone. The adjacent margin of the superior border affords attachment to the Omohyoid muscle.

The **external or axillary border** (*margo axillaris*) is the thickest of the three. It commences above at the lower margin of the glenoid cavity, and inclines obliquely downward and backward to the inferior angle. Immediately below the glenoid cavity is a rough impression, the **infraglenoid tubercle** (*tuberositas infraglenoidalis*), about an inch in length, which affords origin to the long head of the Triceps muscle; in front of this is a longitudinal groove, which extends as far as the lower third of the external border and affords origin to part of the Subscapularis muscle. The inferior third of this border, which is thin and sharp, serves for the origin of a few fibres of the Teres major behind and the Subscapularis in front.

The **internal or vertebral border** (*margo vertebralis*) is the longest of the three, and extends from the internal to the inferior angle of the bone. It is arched, is intermediate in thickness between the superior and the external borders, and the portion of it above the spine is bent considerably outward, so as to form an obtuse angle with the lower part. The internal border presents an anterior lip, a posterior lip, and an intermediate space. The *anterior lip* affords attachment to the Serratus magnus; the *posterior lip*, an origin to the Supraspinatus above the spine, the

Infraspinatus below; to the interval between the two lips, the Levator anguli scapulae is inserted; above the triangular surface at the commencement of the spine, the Rhomboideus minor to the edge of that surface; the Rhomboideus major is attached by means of a fibrous arch connected above to the lower part of the triangular surface at the base of the spine, and below to the lower part of the posterior border.

Angles.—The **internal angle** (*angulus medialis*), formed by the junction of the superior and internal borders, is thin, smooth, rounded, somewhat inclined outward, and gives attachment to a few fibres of the Levator anguli scapulae muscle.

The **inferior angle** (*angulus inferior*), thick and rough, is formed by the union of the vertebral and axillary borders, its posterior surface affording origin to the Teres major and frequently to a few fibres of the Latissimus dorsi.

The **external angle** (*angulus lateralis*) is the thickest part of the bone, and forms what is called the **head** of the scapula. The head presents a shallow, pyriform, articular surface; the **glenoid surface** or **cavity** (*cavitas glenoidalis*), the longest diameter of which is from above downward, and its direction outward and forward. It is broader below than above. Just above it is a rough surface, the **supraglenoid tubercle** (*tuberositas supraglenoidalis*), from which arises the long tendon of the Biceps muscle. The glenoid cavity is covered with cartilage in the recent state; and its margins are slightly raised and give attachment to a fibrocartilaginous structure, the **glenoid ligament**, by which its cavity is deepened. The **neck** of the scapula (*collum scapulae*) is the slightly depressed surface which surrounds the head; it is more distinct on the posterior than on the anterior surface, and below than above. In the latter situation it has arising from it a thick prominence, the **coracoid process**.

The **coracoid process** (*processus coracoideus*) is a thick, curved process of bone which arises by a broad base from the upper part of the neck of the scapula; it is directed at first upward and inward, then, becoming smaller, it changes its direction and passes forward and outward. The ascending portion, flattened from before backward, presents in front a smooth, concave surface over which passes the Subscapularis muscle. The horizontal portion is flattened from above downward, its upper surface is convex and irregular; its under surface is smooth; its inner border is rough, and gives attachment to the Pectoralis minor; its outer border is also rough for the coracoacromial ligament, while the apex is embraced by the conjoined tendon of origin of the short head of the Biceps and of the Coracobrachialis and gives attachment to the costocoracoid ligament. At the inner side of the root of the coracoid process is a rough impression for the attachment of the conoid ligament; and running from it obliquely forward and outward on the upper surface of the horizontal portion, an elevated ridge for the attachment of the trapezoid ligament.

Structure.—In the head, processes, and all the thickened parts of the bone the scapula is composed of cancellous tissue covered by compact bone, while in the rest of its extent it is composed of a thin layer of dense, compact tissue. The central part of the supraspinous fossa and the upper part of the infraspinous fossa, but especially the former, are usually so thin as to be semitransparent; occasionally the bone is found wanting in this situation, and the adjacent muscles come into contact.

Development (Fig. 140).—From *seven* or more centres—one for the body, two for the coracoid process, two for the acromion, one for the vertebral border, and one for the inferior angle. Ossification of the body of the scapula commences about the second month of fetal life by the formation of an irregular quadrilateral plate of bone immediately behind the glenoid cavity. This plate extends itself so as to form the chief part of the bone, the spine growing up from its posterior surface about the third month. At birth a large part of the scapula is osseous, but the glenoid cavity, coracoid and acromion processes, the posterior border, and inferior angle are cartilaginous. From the fifteenth to the eighteenth month after birth

Ossification takes place in the middle of the coracoid process, which usually becomes joined with the rest of the bone at the time when the other centres make their appearance. Between the fourteenth and twentieth years ossification of the remaining centres takes place in quick succession, and in the following order: *first*, in the root of the coracoid process, in the form of a broad scale; *second*, near the base of the acromion process; *third*, in the inferior angle and contiguous part of the posterior border; *fourth*, near the extremity of the acromion; *fifth*, in the posterior border. The acromion process, besides being formed of two separate nuclei, has its base formed by an extension into it of the centre of ossification which belongs to the spine, the extent of which varies in different cases. The two separate nuclei unite and then join with the extension from the spine. These various epiphyses become joined to the bone between the ages of twenty-two and twenty-five years. Sometimes failure of union between the acromion process and spine occurs, the junction being effected by fibrous tissue or by an imperfect articulation; in some cases of supposed fracture of the acromion with ligamentous union it is probable that the detached segment was never united to the rest of the bone. The upper third of the glenoid cavity is usually ossified from a separate centre (*sub-coracoid*) which makes its appearance between the tenth and eleventh years. Very often, in addition, an epiphysis appears for the lower part of the glenoid cavity.

Articulations.—With the humerus and clavicle.

Attachment of Muscles.—To *seventeen*—to the anterior surface, the Subscapularis; posterior surface, Supraspinatus, Infraspinatus; spine, Trapezius, Deltoid; superior border, Omohyoid; vertebral border, Serratus magnus, Levator anguli scapulae, Rhomboideus, minor and major; axillary border, Triceps, Teres minor, Teres major; apex of glenoid cavity, long head of the Biceps; coracoid process, short head of the Biceps, Coracobrachialis, Pectoralis minor; and to the inferior angle occasionally a few fibres of the Latissimus dorsi.

Surface Form.—The only parts of the scapula which are truly subcutaneous are the spine and acromion process, but, in addition to these, the coracoid process, the internal or vertebral border and inferior angle, and, to a less extent, the axillary border, may be defined. The acromion process and spine of the scapula are easily felt throughout their entire length, forming, with the clavicle, the arch of the shoulder. The acromion can be ascertained to be connected to the clavicle at the acromioclavicular joint by running the finger along it, its position being often indicated by an irregularity or bony outgrowth from the clavicle close to the joint. The acromion can be felt forming the point of the shoulder, and from this can be traced backward to join the spine of the scapula. The place of junction is usually denoted by a prominence, which is sometimes called the **acromial angle**. From here the spine of the scapula can be felt as a prominent ridge of bone, marked on the surface as an oblique depression, which becomes less and less distinct, and terminates a little external to the spinous processes of the vertebræ. Its termination is usually indicated by a slight dimple in the skin on a level with the interval between the third and fourth thoracic spines. Below this point the vertebral border of the scapula may be traced, running downward and outward, and thus diverging from the vertebral spines, to the inferior angle of the bone, which can be recognized, although covered by the Latissimus dorsi muscle. From this angle the axillary border can usually be traced through this thick muscular covering, forming, with the muscles, the posterior fold of the axilla. The coracoid

FIG. 140.—Plan of the development of the scapula. From seven centres. The epiphyses (except one for the coracoid process) appear from fifteen to seventeen years, and unite between twenty-two and twenty-five years of age.

process may be felt about an inch below the junction of the middle and outer thirds of the clavicle. Here it is covered by the anterior border of the Deltoid and lies a little to the outer side of a slight depression which corresponds to the interval between the Pectoralis major and Deltoid muscles. When the arms are hanging by the side, the upper angle of the scapula corresponds to the upper border of the second rib or the interval between the first and second thoracic spines, the inferior angle to the upper border of the eighth rib or the interval between the seventh and eighth thoracic spines.

Applied Anatomy.—*Fractures* of the body of the scapula are rare, owing to the mobility of the bone, the thick layer of muscles by which it is encased on both surfaces, and the elasticity of the ribs on which it rests. Fracture of the neck of the bone is also uncommon. The most frequent course of a line of fracture of the neck is from the suprascapular notch to the infraglenoid tubercle (*surgical neck*), and it derives its principal interest from its simulation to a subglenoid dislocation of the humerus. The diagnosis can be made by noting the alteration in the position of the coracoid process. A fracture of the neck external to, and not including, the coracoid process (*anatomical neck*) is said to occur, but it is exceedingly doubtful whether such an accident ever takes place. The acromion process is more frequently broken than any other part of the bone, and there is sometimes, in young subjects, a separation of the epiphysis. It is believed that many of the cases of supposed fracture of the acromion, with fibrous union, which have been found on postmortem examination are really cases of imperfectly united epiphysis. Sir Astley Cooper believed that most fractures of this bone are united by fibrous tissue, and the cause of this mode of union is the difficulty that arises in keeping the fractured ends in constant apposition. The coracoid process is occasionally broken off, either by direct violence or perhaps, rarely, by muscular action.

Tumors of various kinds grow from the scapula. Of the innocent form of tumors, probably the osteomata are the most common. When an osteoma grows from the anterior surface of the scapula, as it sometimes does, it is of the compact variety, such as usually grows from membrane-formed bones, as the bones of the skull. This would appear to afford evidence that this portion of the bone is formed from membrane, and not, like the rest of the bone, from cartilage. Sarcomatous tumors sometimes grow from the scapula, and may necessitate removal of the bone, with or without amputation of the upper limb. Removal of the upper limb with the scapula and the outer two-thirds of the clavicle is known as the *interscapulothoracic amputation*. The scapula may be partially resected or completely excised. There are several methods of complete excision. The bone may be excised by a T-shaped incision, and, the flaps being reflected, the removal is commenced from the vertebral border, so that the subscapular vessels which lie along the axillary border are among the last structures divided, and can be at once secured.

THE ARM.

The **arm** is that portion of the upper extremity which is situated between the shoulder and the elbow. Its skeleton consists of a single bone, the **humerus**.

The Humerus, or Arm Bone (Figs. 141, 142).

The **humerus** is the longest and largest bone of the upper extremity; it presents for examination a shaft and two extremities.

Upper or Proximal Extremity.—The upper extremity presents a large, rounded head, joined to the shaft by a constricted portion, called the neck, and two other eminences, the greater and lesser tuberosities.

The Head (*caput humeri*).—The head, nearly hemispherical in form,¹ is directed upward, inward, and slightly backward, and articulates with the glenoid cavity of the scapula; its surface is smooth and coated with cartilage in the recent state. The circumference of its articular surface is slightly constricted, and is termed the **anatomical neck**, in contradistinction to the constriction which exists below the tuberosities. The latter is called the **surgical neck** (*collum chirurgicum*), as it is often the seat of fracture.

The **anatomical neck** (*collum anatomicum*) is obliquely directed, forming an

¹ Though the head is nearly hemispherical in form, its margin, as Sir G. Humphry has shown, is by no means a true circle. Its greatest measurement is from the top of the bicipital groove in a direction downward, inward, and backward. Hence, it follows that the greatest elevation of the arm can be obtained by rolling the articular surface in this direction—that is to say, obliquely upward, outward, and forward.

FIG. 141.—Left humerus. Anterior view.

obtuse angle with the shaft. It is more distinctly marked in the lower half of its circumference than in the upper half, where it presents a narrow groove, separating the head from the tuberosities. Its circumference affords attachment to the capsular ligament and is perforated by numerous vascular foramina.

The Greater Tuberosity (*tuberculum majus*).—The greater tuberosity is situated on the outer side of the head and lesser tuberosity. Its upper surface is rounded and marked by three flat facets, separated by two slight ridges; the highest facet gives attachment to the tendon of the Supraspinatus; the middle one, to the Infraspinatus; the inferior facet and the shaft of the bone below it, to the Teres minor. The outer surface of the great tuberosity is convex, rough, and continuous with the outer side of the shaft.

The Lesser Tuberosity (*tuberculum minus*).—The lesser tuberosity is more prominent, although smaller than the greater; it is situated in front of the head, and is directed inward and forward. Its summit presents a prominent facet for the insertion of the tendon of the Subscapularis muscle. The tuberosities are separated from each other by a deep groove, the **bicipital groove** (*sulcus intertubercularis*). This groove lodges the long tendon of the Biceps muscle, accompanied by a branch of the anterior circumflex artery. It commences above between the two tuberosities, passes obliquely downward and a little inward, and terminates at the junction of the upper with the middle third of the bone. It is deep and narrow at the commencement, and becomes shallow and a little broader as it descends. In the recent state it is covered with a thin layer of cartilage, lined by a prolongation of the synovial membrane of the shoulder-joint, and receives the tendon of insertion of the Latissimus dorsi muscle.

The Shaft (*corpus humeri*).—The shaft of the humerus is almost cylindrical in the upper half of its extent, prismatic and flattened below, and presents three borders and three surfaces for examination.

The **anterior border** runs from the front of the greater tuberosity above to the coronoid depression below, separating the internal from the external surface. Its upper part is very prominent and rough, forms the *outer lip* of the bicipital groove, and serves for the attachment of the tendon of the Pectoralis major. About its centre it forms the anterior boundary of the rough **deltoid impression** (*tuberositas deltoidea*); below, it is smooth and rounded, affording attachment to the Brachialis anticus muscle.

The **external border** (*margo lateralis*) runs from the back part of the greater tuberosity to the external condyle, and separates the external from the posterior surface. It is rounded and indistinctly marked in its upper half, serving for the attachment of the lower part of the insertion of the Teres minor muscle, and below this of the external head of the Triceps muscle; its centre is traversed by a broad, but shallow, oblique depression, the **musculospiral groove** (*sulcus nervi radialis*); its lower part is marked by a prominent, rough margin, a little curved from behind forward, the **external supracondylar ridge**, which presents an anterior lip for the attachment of the Brachioradialis above and Extensor carpi radialis longior below, a posterior lip for the Triceps, and an intermediate space for the attachment of the external intermuscular septum.

The **internal border** (*margo medialis*) extends from the lesser tuberosity to the internal condyle. Its upper third is marked by a prominent ridge, forming the *internal lip* of the bicipital groove, and gives attachment to the tendon of the Teres major. About its centre is an impression for the attachment of the Coracobrachialis, and just below this is seen the entrance of the **nutrient canal**, directed downward. Sometimes there is a second canal situated at the commencement of the musculospiral groove, for a nutrient artery derived from the superior profunda branch of the brachial artery. The inferior third of this border is raised into a slight ridge, the **internal supracondylar ridge**, which becomes very prominent.

below; it presents an anterior lip for the attachment of the Brachialis anticus muscle, a posterior lip for the internal head of the Triceps muscle, and an intermediate space for the attachment of the internal intermuscular septum.

The **external surface** (*facies anterior lateralis*) is directed outward above, where it is smooth, rounded, and covered by the Deltoid muscle; forward and outward below, where it is slightly concave from above downward, and gives origin to part of the Brachialis anticus muscle. About the middle of this surface is seen a rough, triangular impression for the insertion of the Deltoid muscle, **deltoid impression**, and below this the musculospiral groove, directed obliquely from behind forward and downward, and transmitting the musculospiral nerve and superior profunda artery.

The **internal surface** (*facies anterior medialis*), less extensive than the external, is directed inward above, forward and inward below; at its upper part it is narrow and forms the floor of the bicipital groove; to it is attached the Latissimus dorsi. The middle part of this surface is slightly roughened for the attachment of some of the fibres of the tendon of insertion of the Coracobrachialis; its lower part is smooth, concave from above downward, and gives attachment to the Brachialis anticus muscle.¹ A little below the middle of the shaft is the nutrient canal, which is directed toward the elbow-joint.

The **posterior surface** (*facies posterior*) (Fig. 142) appears somewhat twisted, so that its upper part is directed a little inward, its lower part backward and a little outward. Nearly the whole of this surface is covered by the external and internal heads of the

FIG. 142.—Left humerus. Posterior surface.

¹ A small hook-shaped process of bone, the *supracondylar process*, varying from $\frac{1}{10}$ to $\frac{3}{16}$ of an inch in length, is not infrequently found projecting from the inner surface of the shaft of the humerus two inches above the internal condyle. It is curved downward, forward, and inward, and its pointed extremity is connected to the internal border, just above the inner condyle, by a ligament or fibrous band, which gives origin to a portion of the Pronator teres; through the arch completed by this fibrous band the median nerve and brachial artery pass when these structures deviate from their usual course. Sometimes the nerve alone is transmitted through it, or the nerve may be accompanied by the ulnar artery in cases of high division of the brachial. A well-marked groove is usually found behind the process in which the nerve and artery are lodged. This space is analogous to the supracondylar foramen in many animals, and probably serves in them to protect the nerve and artery from compression during the contraction of the muscles in this region.

Triceps, the former of which is attached to its upper and outer part, the latter to its inner and back part, the two being separated by the musculospiral groove.

The **Lower or Distal Extremity** is flattened from before backward, and curved slightly forward; it terminates below in a broad, articular surface which is divided into two parts by a slight ridge. Projecting on either side are the external and internal condyles. By some anatomists the external condyle is called the external epicondyle and the internal condyle is called the internal epicondyle. The **articular surface** extends a little lower than the condyles, and is curved slightly forward, so as to occupy the more anterior part of the bone; its greatest breadth is in the transverse diameter, and it is obliquely directed, so that its inner extremity occupies a lower level than the outer. The outer portion of the articular surface presents a smooth, rounded eminence, which has received the name of the **capitellum**, or **radial head** of the humerus (*capitulum humeri*); it articulates with the cup-shaped depression on the head of the radius, and is limited to the front and lower part of the bone, not extending as far back as the other portion of the articular surface. On the inner side of this eminence is a shallow groove, in which is received the inner margin of the head of the radius. Above the front part of the capitellum is a slight depression, the **radial fossa** (*fossa radialis*), which receives the anterior border of the head of the radius when the forearm is flexed. The inner portion of the articular surface, the **trochlea** (*trochlea humeri*), presents a deep depression between two well-marked borders. This surface is convex from before backward, concave from side to side, and occupies the anterior, lower, and posterior parts of the bone. The **external border**, less prominent than the internal, corresponds to the interval between the radius and the ulna. The **internal border** is thicker, more prominent, and consequently of greater length, than the external. The grooved portion of the articular surface fits accurately within the greater sigmoid cavity of the ulna; it is broader and deeper on the posterior than on the anterior aspect of the bone, and is inclined obliquely from behind forward and from without inward. Above the front part of the trochlear surface is seen a smaller depression, the **coronoid fossa** (*fossa coronoidea*), which receives the coronoid process of the ulna during flexion of the forearm. Above the back part of the trochlear surface is a deep, triangular depression, the **olecranon fossa** (*fossa olecrani*), in which is received the summit of the olecranon process in extension of the forearm. These fossæ are separated from one another by a thin, transparent lamina of bone, which is sometimes perforated by a foramen, the **supratrochlear foramen**; their upper margins afford attachment to the anterior and posterior ligaments of the elbow-joint, and they are lined, in the recent state, by the synovial membrane of this articulation. The articular surfaces, in the recent state, are covered with a thin layer of hyaline cartilage. The **external condyle** (*epicondylus lateralis*) is a small, tubercular eminence, less prominent than the internal, curved a little forward, and giving attachment to the external lateral ligament of the elbow-joint, and to a tendon common to the origin of some of the Extensor and Supinator muscles. The **internal condyle** (*epitrochlea* or *epicondylus medialis*), larger and more prominent, is directed a little backward; it gives attachment to the internal lateral ligament, to the Pronator teres, and to a tendon common to the origin of some of the Flexor muscles of the forearm. The ulnar nerve runs in a groove, the **ulnar groove** (*sulcus nervi ulnaris*), at the back of the internal condyle, or between it and the olecranon process. These condyles are directly continuous above with the external and internal supracondylar ridges.

Structure.—The extremities consist of cancellous tissue, covered with a thin compact layer; the shaft is composed of a cylinder of compact tissue, thicker at the centre than at the extremities, and hollowed out by a large medullary canal, which extends along its whole length. In the head of the humerus the plates of the cancellous tissue are arranged in curves (Fig. 143), known as **pressure curves**. Most of the bone plates are at right angles to the plane of the

articular surface (the lines of greatest pressure), and they are bound together by other bone fibres, which usually correspond to the plane of the articulation (the lines of greatest tension). This arch-like arrangement strengthens the head of the bone, and it is further strengthened by the binding fibres.

Development.—From *eight* centres (Fig. 144), one for each of the following parts: The shaft, head, each tuberosity, the radial head, the trochlear portion of the articular surface, and each condyle. The nucleus for the shaft appears near the centre of the bone in the eighth week, and soon extends toward the extremities. At birth the humerus is ossified nearly in its whole length, the extremities remaining cartilaginous. During the first year, sometimes even before birth, ossification commences in the head of the bone, and during the third year the centre for the greater tuberosity makes its appearance, that for the lesser being small and not appearing until the fifth year. By the sixth year the centres for the head and tuberosities have increased in size and become joined, so as to form a single large epiphysis.

FIG. 143.—Longitudinal section of head of left humerus.

FIG. 144.—Plan of the development of the humerus from eight centres.

The lower end of the humerus is developed in the following manner: At the end of the second year ossification commences in the capitellum, and from this point extends inward, so as to form the chief part of the articular end of the bone, the centre for the inner part of the trochlea not appearing until about the age of twelve. Ossification commences in the internal condyle about the fifth year, and in the external one not until about the thirteenth or fourteenth year. About the sixteenth or seventeenth year the outer condyle and both portions of the articulating surface (which have already joined) unite with the shaft; at the eighteenth year the inner condyle becomes joined; while the upper epiphysis, although the first formed, is not united until about the twentieth year.

Articulations.—With the glenoid cavity of the scapula and with the ulna and radius.

Attachment of Muscles.—To *twenty-four*—to the greater tuberosity, the Supraspinatus, Infraspinatus, and Teres minor; to the lesser tuberosity, the Subscapularis; to the external bicipital ridge, the Pectoralis major; to the internal bicipital ridge, the Teres major; to the bicipital groove, the Latissimus dorsi; to the shaft, the Deltoid, Coracobrachialis, Brachialis anticus, external and internal heads of the Triceps; to the internal condyle, the Pronator teres, and common tendon of the Flexor carpi radialis, Palmaris longus, Flexor sublimis digitorum, and Flexor carpi ulnaris; to the external, supracondylar ridge, the Brachioradialis and Extensor carpi radi-

alis longior; to the external condyle, the common tendon of the Extensor carpi radialis brevior, Extensor communis digitorum, Extensor minimi digiti, Extensor carpi ulnaris, and Supinator [brevis]; to the back of the external condyle, the Anconeus.

Surface Form.—The humerus is almost entirely clothed by the muscles which surround it, and the only parts of this bone which are strictly subcutaneous are small portions of the internal and external condyles. In addition to these, the tuberosities and a part of the head of the bone can be felt under the skin and muscles by which they are covered. Of these, the greater tuberosity forms the most prominent bony point of the shoulder, extending beyond the acromion process and covered by the Deltoid muscle. It influences materially the surface form of the shoulder. It is best felt while the arm is lying loosely by the side; if the arm be raised, it recedes from under the finger. The lesser tuberosity, directed forward and inward, is to be felt to the inner side of the greater tuberosity, just below the acromioclavicular joint. Between the two tuberosities lies the bicipital groove. This can be defined by placing the finger and making firm pressure just internal to the greater tuberosity; then, by rotating the humerus, the groove will be felt to pass under the finger as the bone is rotated. With the arm abducted from the side, by pressing deeply in the axilla the lower part of the head of the bone is to be felt. On each side of the elbow-joint, and just above it, the internal and external condyles of the bone may be felt. Of these, the internal is the more prominent, but the ridge passing upward from it, the internal supracondylar ridge, is much less marked than the external, and, as a rule, is not to be felt. Occasionally, however, we find along this border the hook-shaped process mentioned above. The external condyle is most plainly to be seen during semiflexion of the forearm, and its position is indicated by a depression between the attachment of the adjacent muscles. From it is to be felt a strong bony ridge running up the outer border of the shaft of the bone. This is the external supracondylar ridge; it is concave forward, and corresponds with the curved direction of the lower extremity of the humerus.

Applied Anatomy.—There are several points of surgical interest connected with the humerus. First, as regards its development. The upper end, though the first to ossify, is the last to join the shaft, and the length of the bone is mainly due to growth from this upper epiphysis. Hence, in cases of *amputation of the arm* in young subjects the humerus continues to grow considerably, and the end of the bone, which immediately after the operation was covered with a thick cushion of soft tissue, begins to project, thinning the soft parts and rendering the *stump conical*. This may necessitate another operation, which consists in the removal of a couple of inches or so of the bone, and even after this operation a recurrence of the conical stump may take place.

There are several points of surgical interest in connection with *fractures*. First, as regards their causation, the bone may be broken by direct or indirect violence like the other long bones, but, in addition to this, it is probably more frequently fractured by muscular action than any other of this class of bone in the body. It is usually the shaft, just below the insertion of the Deltoid, which is thus broken. Fractures of the upper end may take place through the anatomical neck, through the surgical neck, or separation of the greater tuberosity may occur. Fracture of the anatomical neck is a very rare accident; in fact, it is doubted by some whether it ever occurs. These fractures are usually considered to be *intracapsular*, but they are probably partly within and partly without the capsule, as the lower part of the capsule is inserted some little distance below the anatomical neck, while the upper part is attached to it. They may be *impacted* or *nonimpacted*. In most cases there is little or no displacement on account of the capsule, in whole or in part, remaining attached to the lower fragment. Separation of the *upper epiphysis* of the humerus sometimes occurs in the young subject, and is marked by a characteristic deformity by which the lesion may be at once recognized. This consists in the presence of an abrupt projection at the front of the joint a short distance below the coracoid process, caused by the upper end of the lower fragment. In fractures of the *shaft of the humerus* the lesion may take place at any point, but appears to be more common in the lower than in the upper part of the bone. The points of interest in connection with these fractures are: (1) That the musculospiral nerve may be injured as it lies in the groove on the bone; or may become involved in the callus which is subsequently thrown out; and (2) the frequency of nonunion. This is believed to be more common in the humerus than in any other bone, and various causes have been assigned for it. It would seem most probably to be due to the difficulty that there is in fixing the shoulder-joint and the upper fragment, and possibly the elbow-joint and lower fragment also. Other causes which have been assigned for the nonunion are: (1) That in attempting passive motion of the elbow-joint to overcome any rigidity which may exist, the movement does not take place at the articulation, but at the seat of fracture; or that the patient, in consequence of the rigidity of the elbow, in attempting to flex or extend the forearm moves the fragment and not the joint. (2) The presence of small portions of muscle tissue between the broken ends. (3) Want of support to the elbow, so that the weight of the arm tends to drag the lower fragment away from the upper. An important distinction to make in fractures of the *lower end of the humerus* is between those that involve the elbow-joint and those which do not; the former are always serious, as they may lead to stiffness of the joint and impairment of the

utility of the limb. They include the T-shaped fracture and oblique fractures which involve the articular surface. The fractures which do not involve the joint are the transverse above the condyles and the so-called epitrochlear fracture, in which the tip of the internal condyle is broken off, generally by direct violence.

Under the head of *separation of the lower epiphysis* two separate injuries have been described: (1) Where the whole of the four ossific centres which form the lower extremity of the bone are separated from the shaft; and (2) where the articular portion is alone separated, the two condyles remaining attached to the shaft of the bone. The *epiphyseal line* between the shaft and lower end runs across the bone just above the tips of the condyles, a point to be borne in mind in performing the operation of excision. Shortening may follow *epiphysitis*.

Tumors originating from the humerus are of frequent occurrence. A not uncommon place for a *chondroma* to grow from is the shaft of the bone somewhere in the neighborhood of the insertion of the deltoid. *Sarcomata* frequently grow from this bone.

THE FOREARM.

The **forearm** is that portion of the upper extremity which is situated between the elbow and the wrist. Its skeleton is composed of two bones, the **ulna** and **radius**.

The Ulna, or Elbow Bone (Figs. 145, 147).

The **ulna** is a long bone, prismatic in form, placed at the inner side of the forearm, parallel with the radius. It is the larger and longer of the two bones. Its upper extremity, of great thickness and strength, forms a large part of the articulation of the elbow-joint; it diminishes in size from above downward, its lower extremity being very small, and excluded from the wrist-joint by the interposition of an intra-articular fibrocartilage. It is divisible into a shaft and two extremities.

The **Upper or Proximal Extremity**, the strongest part of the bone, presents for examination two large, curved processes, the olecranon process and the coronoid process; and two concave, articular cavities, the greater and lesser sigmoid cavities.

The **olecranon process** (*olecranon*) is a large, thick, curved eminence situated at the upper and back part of the ulna. It is curved forward at the summit so as to present a prominent tip which is received into the olecranon fossa of the humerus in extension of the forearm, its base being contracted where it joins the shaft. This is the narrowest part of the upper end of the ulna. The *posterior surface* of the olecranon, directed backward, is triangular, smooth, subcutaneous, and covered by a bursa. Its *upper surface* is of a quadrilateral form, marked behind by a rough impression for the attachment of the Triceps muscle; and in front, near the margin, by a slight transverse groove for the attachment of part of the posterior ligament of the elbow-joint. Its *anterior surface* is smooth, concave, covered with cartilage in the recent state, and forms the upper and back part of the greater sigmoid cavity. The *lateral borders* present a continuation of the same groove that was seen on the margin of the superior surface; they serve for the attachment of ligaments—viz., the back part of the internal lateral ligament internally, the posterior ligament externally. To the *inner border* is also attached a part of the Flexor carpi ulnaris, while to the *outer border* is attached the Anconeus muscle.

The **coronoid process** (*processus coronoideus*) is a triangular eminence of bone which projects horizontally forward from the upper and front part of the ulna. Its *base* is continuous with the shaft, and of considerable strength; so much so that fracture of it is an accident of rare occurrence. Its *apex* is pointed, slightly curved upward, and is received into the coronoid depression of the humerus in

FIG. 145.—Bones of the left forearm. Anterior view.

flexion of the forearm. Its *upper surface* is smooth, concave, and forms the lower part of the greater sigmoid cavity. The *under surface* is concave. At the junction of this surface with the shaft is a rough eminence, the **tubercle of the ulna** (*tuberositas ulnae*), for the attachment of the oblique ligament of the middle radioulnar articulation and the Brachialis anticus muscle. Its outer surface presents a narrow, oblong, articular depression, the **lesser sigmoid cavity**. The *inner surface*, by its prominent, free margin, serves for the attachment of part of the internal lateral ligament. At the front part of this surface is a small, rounded eminence for the attachment of one head of the Flexor sublimis digitorum; behind the eminence, a depression for part of the origin of the Flexor profundus digitorum; and, descending from the eminence, a ridge which gives attachment to one head of the Pronator teres. Generally, the Flexor longus pollicis has an origin from the lower part of the coronoid process by a rounded bundle of muscle fibres.

The **greater sigmoid cavity** (*incisura semilunaris*) is a semilunar depression of large size, formed by the olecranon and coronoid processes, and serving for articulation with the trochlear surface of the humerus. About the middle of either lateral border of this cavity is a notch which contracts it somewhat, and serves to indicate the junction of the two processes of which it is formed. The cavity is concave from above downward, and divided into two lateral parts by a smooth, elevated ridge which runs from the summit of the olecranon to the tip of the coronoid process. Of these two portions, the internal is the larger, and is slightly concave transversely; the external portion is convex above, slightly concave below. The articular surface, in the recent state, is covered with a thin layer of hyaline cartilage.

The **lesser sigmoid cavity** (*incisura radialis*) is a narrow, oblong, articular depression, placed on the outer side of the coronoid process, and receives the lateral articular surface of the head of the radius. It is concave from before backward, and its extremities, which are prominent, serve for the attachment of the orbicular ligament. In the recent state it is covered with a thin layer of hyaline cartilage.

The **Shaft** (*corpus ulnae*), at its upper part, is prismatic in form, and curved from behind forward and from without inward, so as to be convex behind and externally; its central part is quite straight; its lower part rounded, smooth, and bent a little outward; it tapers gradually from above downward, and presents for examination three borders and three surfaces.

The **anterior or palmar border** (*margo volaris*) commences above at the prominent inner angle of the coronoid process, and terminates below in front of the styloid process. It is well marked above, smooth and rounded in the middle of its extent, and affords origin to the Flexor profundus digitorum; its lower fourth, marked off from the rest of the border by the commencement of an oblique ridge on the anterior surface, serves for the origin of the Pronator quadratus. It separates the anterior from the internal surface.

The **posterior or dorsal border** (*margo dorsalis*) commences above at the apex of the triangular subcutaneous surface at the back part of the olecranon, and

FIG. 146.—Upper extremity of left ulna. Outer aspect.

terminates below at the back part of the styloid process; it is well marked in the upper three-fourths, and gives origin to the aponeurosis common to the Flexor carpi ulnaris, the Extensor carpi ulnaris, and the Flexor profundus digitorum muscles; its lower fourth is smooth and rounded. This border separates the internal from the posterior surface.

The **external or interosseous border** (*crista interossea*) commences above by the union of two lines, which converge one from each extremity of the lesser sigmoid cavity, enclosing between them a triangular space for the origin of part of the Supinator [brevis], and terminates below at the middle of the lower extremity. Its two middle fourths are very prominent; its lower fourth is smooth and rounded. This border gives attachment to the interosseous membrane, and separates the anterior from the posterior surface.

The **anterior or palmar surface** (*facies volaris*) lies between the anterior and external borders, is much broader above than below, is concave in the upper three-fourths of its extent, and affords origin to the Flexor profundus digitorum; its lower fourth, also concave, is covered by the Pronator quadratus. The lower fourth is separated from the remaining portion of the bone by a prominent ridge (*pronator ridge*) directed obliquely from above downward and inward; this ridge marks the extent of attachment of the Pronator quadratus. At the junction of the upper with the middle third of the bone is the **nutrient foramen**. It opens into the **nutrient canal**, which is directed obliquely inward and upward (proximally).

The **posterior, dorsal, or extensor surface** (*facies dorsalis*) is bounded internally by the interosseous border, externally by the posterior border, and is directed backward and outward; it is broad and concave above, somewhat narrower and convex in the middle of its course, narrow, smooth, and rounded below. It presents, above, an oblique ridge, which runs from the posterior extremity of the lesser sigmoid cavity, downward to the posterior border; the triangular surface above this ridge receives the insertion of the Anconeus muscle, while the upper part of the ridge itself affords origin to the Supinator. The surface of bone below this is subdivided by a longitudinal ridge into two parts; the internal part is smooth, and covered by the Extensor carpi ulnaris; the external portion, wider and rougher, gives origin from above downward to part of the Supinator, the Extensor ossis metacarpi pollicis, the Extensor longus pollicis, and the Extensor indicis muscles.

The **internal surface** (*facies medialis*) is broad and concave above, narrow and convex below. It gives origin by its upper three-fourths to the Flexor profundus digitorum muscle; its lower fourth is subcutaneous. The anterior and the inner surfaces constitute the **flexor surface**.

The **Distal or Lower Extremity** is of small size, and excluded from the articulation of the wrist-joint. It presents for examination two eminences, the outer and larger of which is a rounded, articular eminence, termed the **head** (*capitulum ulnae*), the inner, narrower and more projecting, is a nonarticular eminence, the **styloid process** (*processus styloideus*). The head presents an articular facet, part of which, of an oval form, is directed downward, and plays on the upper surface of the triangular fibrocartilage which separates it from the wrist-joint; the remaining portion, directed outward, is narrow, convex, and received into the sigmoid cavity of the radius. The **styloid process** projects from the inner and back part of the bone, and descends a little lower than the head, terminating in a rounded summit, which affords attachment to the internal lateral ligament of the wrist. The head is separated from the styloid process by a depression for the attachment of the triangular intra-articular fibrocartilage; and behind, by a shallow groove for the passage of the tendon of the Extensor carpi ulnaris.

Structure.—Similar to that of the other long bones.

Development.—From *three* centres—one for the shaft, one for the inferior extremity, and one for the olecranon (Fig. 148). Ossification commences near the middle of the shaft about the eighth week, and soon extends through the greater part of the bone. At birth the ends are cartilaginous. About the fourth year a separate osseous nucleus appears in the middle of the head, which soon extends into the styloid process. About the tenth year ossific material appears in the olecranon near its extremity, the chief part of this process being formed from an extension of the shaft of the bone into it. At about the sixteenth year the upper epiphysis becomes joined to the shaft, and at about the twentieth year the lower one.

Articulations.—With the humerus and radius.

Attachment of Muscles.—To *sixteen*: To the olecranon, the Triceps, Anconeus, and one head of the Flexor carpi ulnaris. To the coronoid process, the Brachialis anticus, Pronator teres,

Flexor sublimis digitorum, and Flexor profundus digitorum; generally also the Flexor longus pollicis. To the shaft, the Flexor profundus digitorum, Pronator quadratus, Flexor carpi ulnaris, Extensor carpi ulnaris, Anconeus, Supinator [brevis], Extensor ossis metacarpi pollicis, Extensor longus pollicis, and Extensor indicis.

Surface Form.—The most prominent part of the ulna on the surface of the body is the olecranon process, which can always be felt at the back of the elbow-joint. When the forearm is flexed, the upper quadrilateral surface can be felt, directed backward; during extension it recedes into the olecranon fossa, and the contracting fibres of the triceps prevent its being perceived. At the back of the olecranon is the smooth, triangular, subcutaneous surface, which below is continuous with the posterior border of the shaft of the bone, and felt in every position of the forearm. During extension the upper border of the olecranon is slightly above the level of the internal condyle, and the process itself is nearer to this condyle than the outer one. Running down the back of the forearm, from the apex of the triangular surface which forms the posterior surface of the olecranon, is a prominent ridge of bone, the posterior border of the ulna. This may be felt throughout the entire length of the shaft of the bone, from the olecranon above to the styloid process below. As it passes down the forearm it pursues a sinuous course and inclines to the inner side, so that, though it is situated in the middle of the back of the limb above, it is on the inner side of the wrist at its termination. It becomes rounded off in its lower third, and may be traced below to the small, subcutaneous surface of the styloid process. Internal to this border the lower fourth of the inner surface may be felt. The styloid process may be

FIG. 148.—Plan of the development of the ulna. From three centres.

felt as a prominent tubercle of bone, continuous above with the posterior subcutaneous border of the ulna, and terminating below in a blunt apex, which lies a little internal and behind, but on a level with, the wrist-joint. The styloid process is best felt when the hand is in the same line as the bones of the forearm, and in a position midway between supination and pronation. If the forearm is pronated while the finger is placed on the process, it will be felt to recede, and another prominence of bone will appear just behind and above it. This is the head of the ulna, which articulates with the lower end of the radius and the triangular intra-articular fibrocartilage, and now projects between the tendons of the Extensor carpi ulnaris and the Extensor minimi digiti muscles.

The Radius.

The **radius** is situated on the outer side of the forearm, lying side by side with the ulna, which exceeds it in length and size (Fig. 145). Its upper end is small, and forms only a small part of the elbow-joint; but its lower end is large, and forms the chief part of the wrist. It is one of the long bones, prismatic in form, slightly curved longitudinally, and, like other long bones, has a shaft and two extremities.

The **Proximal** or **Upper Extremity** presents a head, neck, and tuberosity.

The **head** (*capitulum radii*) is of a cylindrical form, depressed on its upper surface into a shallow cup (*fovea capituli radii*), which articulates with the capitulum or radial head of the humerus. In the recent state it is covered with a layer

of cartilage which is thinnest at its centre. Around the circumference of the head is a smooth, articular surface (*circumferentia articularis*), broad internally where it articulates with the lesser sigmoid cavity of the ulna; narrow in the rest of its circumference, where it rotates within the orbicular ligament. It is coated with hyaline cartilage in the recent state. The head is supported on a round, smooth, and constricted portion of bone, called the **neck** (*collum radii*), which presents, behind, a slight ridge, for the attachment of part of the Supinator [brevis]. Beneath the neck, at the inner and front aspect of the bone, is a rough eminence, the **bicipital tuberosity** (*tuberositas radii*). Its surface is divided into two parts by a vertical line—a posterior, rough portion, for the insertion of the tendon of the Biceps muscle; and an anterior, smooth portion, on which a bursa is interposed between the tendon and the bone.

The **Shaft** (*corpus radii*) is prismoid in form, narrower above than below, and slightly curved, so as to be convex outward. It presents three surfaces, separated by three borders.

The **anterior or palmar border** (*margo volaris*) extends from the lower part of the tuberosity above to the anterior part of the base of the styloid process below. It separates the anterior from the external surface. Its upper third is very prominent; and from its oblique direction, downward and outward, has received the name of the **oblique line of the radius**. It gives insertion externally to the Supinator [brevis] internally, it limits the origin of the Flexor longus pollicis, and between these, arising from it, is the radial origin of the Flexor sublimis digitorum. The middle third of the anterior border is indistinct and rounded. Its lower fourth is sharp, prominent, affords attachment to the Pronator quadratus and to the posterior annular ligament of the wrist, and terminates in a small tubercle at the base of the styloid process, into which is inserted the tendon of the Brachioradialis.

The **posterior or dorsal border** (*margo dorsalis*) commences above at the back part of the neck of the radius, and terminates below at the posterior part of the base of the styloid process; it separates the posterior from the external surface. It is indistinct above and below, but well marked in the middle third of the bone.

The **internal or interosseous border** (*crista interossea*) commences above at the back part of the tuberosity, where it is rounded and indistinct, becomes sharp and prominent as it descends, and at its lower part divides into two ridges, which descend to the anterior and posterior margins of the sigmoid cavity. This border separates the anterior from the posterior surface, and has the interosseous membrane attached to it throughout the greater part of its extent.

The **anterior or palmar or flexor surface** (*facies volaris*) is concave for its upper three-fourths, and gives origin to the Flexor longus pollicis muscle; it is broad and flat for its lower fourth, and gives attachment to the Pronator quadratus. A prominent ridge limits the attachment of the Pronator quadratus below, and between this and the inferior border is a triangular rough surface for the attachment of the anterior ligament of the wrist-joint. At the junction of the upper and middle third of this surface is the **nutrient foramen**, the opening of the **nutrient canal**, which is directed obliquely upward (proximally).

The **posterior or dorsal or extensor surface** (*facies dorsalis*) is rounded, convex, and smooth in the upper third of its extent, and covered by the Supinator [brevis] muscle. Its middle third is broad, slightly concave, and gives origin to the Extensor ossis metacarpi pollicis above, the Extensor brevis pollicis below. Its lower third is broad, convex, and covered by the tendons of the muscles, which subsequently run in the grooves on the lower end of the bone.

The **external surface** (*facies lateralis*) is rounded and convex throughout its entire extent. Its upper third gives attachment to the Supinator [brevis] muscle. About its centre is seen a rough ridge, for the insertion of the Pronator teres muscle. Its lower part is narrow, and covered by the tendons of the Extensor ossis metacarpi pollicis and Extensor brevis pollicis muscles.

The **Lower Extremity** is large, of quadrilateral form, and provided with two articular surfaces—one at the extremity, for articulation with the carpus, and one at the inner side of the bone, for articulation with the ulna. The **carpal articular surface** (*facies articularis carpea*) is of triangular form, concave, smooth, and divided by a slight antero-posterior ridge into two parts. Of these, the external is of a triangular form, and articulates with the scaphoid bone; the inner is quadrilateral and articulates with the semilunar bone. The articular surface for the head of the ulna is called the **sigmoid cavity of the radius** (*incisura ulnaris*); it is narrow, concave, smooth, and articulates with the head of the ulna. The circumference of this end of the bone presents three surfaces—an anterior, external, and posterior. The *anterior surface*, rough and irregular, affords attachment to the anterior ligament of the wrist-joint. The *external surface* is prolonged obliquely downward into a strong conical projection, the **styloid process** (*processus styloideus*), which gives attachment by its base to the tendon of the Brachioradialis, and by its apex to the external lateral ligament of the wrist-joint. The outer surface of this process is marked by a flat groove, which runs obliquely downward and forward, and gives passage to the tendons of the Extensor ossis metacarpi pollicis and the Extensor brevis pollicis. The *posterior surface* is convex, affords attachment to the posterior ligament of the wrist, and is marked by three grooves. Proceeding from without inward, the first groove is broad but shallow, and subdivided into two by a slightly elevated ridge; the outer of these two transmits the tendon of the Extensor carpi radialis longior, the inner the tendon of the Extensor carpi radialis brevior. The second, which is near the centre of the bone, is a deep but narrow groove, bounded on its outer side by a sharply defined ridge; it is directed obliquely from above, downward and outward, and transmits the tendon of the Extensor longus pollicis. The third, lying most internally, is a broad groove, for the passage of the tendons of the Extensor indicis and Extensor communis digitorum.

Structure.—Similar to that of the other long bones.

Development (Fig. 149).—From *three centres*, *one* for the shaft and *one* for each extremity. That for the shaft makes its appearance near the centre of the bone, about the eighth week of fetal life. About the end of the second year ossification commences in the lower epiphysis, and about the fifth year in the upper end. At the age of seventeen or eighteen the upper epiphysis becomes joined to the shaft, the lower epiphysis becoming united about the twentieth year. Sometimes an additional centre appears about the fourteenth year in the bicipital tuberosity.

Articulation.—With *four bones*—the humerus, ulna, scaphoid, and semilunar.

Attachment of Muscles.—To *nine*: To the tuberosity, the Biceps; to the oblique ridge, the Supinator [brevis], Flexor sublimis digitorum, and Flexor longus pollicis; to the shaft (its anterior surface), the Flexor longus pollicis and Pronator quadratus; (its posterior surface), the Extensor ossis metacarpi pollicis and Extensor brevis pollicis; (its outer surface), the Pronator teres; and to the styloid process, the Brachioradialis.

Surface Form.—Just below and a little in front of the posterior surface of the external condyle a part of the head of the radius may be felt, covered by the orbicular and external lateral ligaments. There is in this situation a little dimple in the skin, which is most visible when the arm is extended, and which marks the position of the head of the bone. If the finger is placed on this dimple and the forearm pronated and supinated, the head of the bone will be distinctly perceived rotating in the lesser sigmoid cavity. The upper half of the shaft of the radius cannot be felt, as it is surrounded by the fleshy bellies of the muscles arising from the external condyle. The lower half of the shaft can be readily examined, though covered by tendons and muscles and not strictly subcutaneous. If traced downward, the shaft will be felt to terminate in a lozenge-shaped, convex surface on the outer side of the base of the styloid process. This is the only subcutaneous part of the bone, and from its lower extremity the apex of the styloid process will be felt bending inward toward the wrist. About the middle of the posterior aspect of the lower extremity of the bone is a well-marked ridge, best perceived when the hand is slightly flexed on the wrist. It forms the outer boundary of the oblique groove on the posterior surface of the bone, through which the tendon of the Extensor longus pollicis runs, and serves to keep that tendon in place.

Applied Anatomy of the Radius and Ulna.—The two bones of the forearm are more often broken together than is either the radius or ulna separately. It is therefore convenient to consider *fractures* of both bones in the first instance, and subsequently to mention the principal fractures

which take place in each bone individually. These fractures may be produced by either direct or indirect violence, though more commonly by direct violence. When indirect force is applied to the forearm the radius generally alone gives way, though both bones may suffer. The fracture from indirect force generally takes place somewhere about the middle of the bones; fracture from direct violence may occur at any part, more often, however, in the lower half of the bone. The fracture is usually transverse, but may be more or less oblique. A point of interest in connection with these fractures is the tendency that there is for the two bones to unite across the interosseous membrane; the limb should therefore be put up in a position midway between supination and pronation, which is not only the most comfortable position, but also separates the bones most widely from each other, and therefore diminishes the risk of the bones becoming united across the interosseous membrane. The splints, anterior and posterior, which are applied in these cases should be rather wider than the limb, so as to prevent any lateral pressure on the bones. In these cases there is a greater liability to gangrene from the pressure of the splints than in other parts of the body. This is no doubt due principally to two causes: (1) The flexion of the forearm compressing to a certain extent the brachial artery and retarding the flow of blood to the limb; and (2) the superficial position of the two main arteries of the forearm in a part of their course, and their liability to be compressed by the splints. The special fractures of the ulna are: (1) Fracture of the olecranon. This may be caused by direct violence, falls on the elbow with the forearm flexed, or by muscular action by the sudden contraction of the triceps. The most common place for the fracture to occur is at the constricted portion where the olecranon joins the shaft of the bone, and the fracture may be either transverse or oblique; but any part may be broken, even a thin shell may be torn off. Fractures from direct violence are occasionally comminuted. The displacement is sometimes very slight, owing to the fibrous structures around the process not being torn. (2) Fracture of the coronoid process sometimes occurs as a complication of dislocation backward of the bones of the forearm, but it is doubtful if it ever occurs as an uncomplicated injury. (3) Fractures of the shaft of the ulna may occur at any part, but usually takes place at the middle of the bone or a little below it. They are usually the result of direct violence. (4) The styloid process may be knocked off by direct violence. Fractures of the radius consist of: (1) Fracture of the head of the bone; this generally occurs in conjunction with some other lesion, but may occur as an uncomplicated injury. (2) Fracture of the neck may also take place, but is generally complicated with other injury. (3) Fractures of the shaft of the radius are very common, and may take place at any part of the bone. They may take place from either direct or indirect violence. In fractures of the upper third of the shaft of the bone, that is to say, above the insertion of the Pronator teres, the displacement is very great. The upper fragment is strongly supinated by the Biceps and Supinator, and flexed by the Biceps, while the lower fragment is pronated and drawn toward the ulna by the two pronators. If such a fracture is put up in the ordinary position, midway between supination and pronation, the fracture will unite with the upper fragment in a position of supination, and the lower one in the mid-position, and thus considerable impairment of the movements of the hand will result. The limb should be put up with the forearm supinated. (4) The most important fracture of the radius is that of the lower end (*Colles' fracture*). The fracture is transverse, and generally takes place about an inch from the lower extremity. It is caused by falls on the palm of the hand, and is an injury of advanced life, occurring more frequently in the female than the male. In consequence of the manner in which the fracture is caused, the upper fragment becomes driven into the lower, and impaction is the result; or else the lower fragment becomes split up into two or more pieces, so that no fixation occurs. Separation of the lower epiphysis of the radius may take place in the young. This injury and Colles' fracture may be distinguished from other injuries in this neighborhood—especially dislocation, with which it is liable to be confounded—by observing the relative positions of the styloid processes of the ulna and radius. In the natural condition of parts, with the arm hanging by the side, the styloid process of the radius is on a lower level than that of the ulna; that is to say, nearer the ground. After fracture or separation of the epiphysis this process is on the same or a higher level than that of the ulna, whereas it would be unaltered in position in dislocation.

FIG. 149.—Plan of the development of the radius. From three centres.

THE HAND.

The skeleton of the hand is subdivided into three segments—the **carpus**, or wrist bones; the **metacarpus**, or bones of the palm; and the **phalanges**, or bones of the digits.

FIG. 150.—Bones of the left hand. Dorsal surface.

The Carpus (Ossa Carpi) (Figs. 150, 151).

The bones of the **carpus**, *eight* in number, are arranged in two rows. Those of the upper row, enumerated from the radial to the ulnar side, are the **scaphoid**,

FIG. 151.—Bones of the left hand. Palmar surface.

semilunar, cuneiform, and pisiform; those of the lower row, enumerated in the same order, are the **trapezium, trapezoid, os magnum, and unciform**.

Common Characters of the Carpal Bones.—Each bone (excepting the pisiform) presents six surfaces. Of these the *anterior*, *palmar*, or *volar*, and the *posterior* or *dorsal* are rough for ligamentous attachment, the dorsal surface being the broader, except in the scaphoid and semilunar. The *superior* or *proximal* and *inferior* or *distal* are articular, the superior generally convex, the inferior concave; and the *internal* and *external* are also articular when in contact with contiguous bones, otherwise rough and tubercular. The structure of all is similar, consisting of cancellous tissue enclosed in a layer of compact bone. Each bone is also developed from a single centre of ossification.

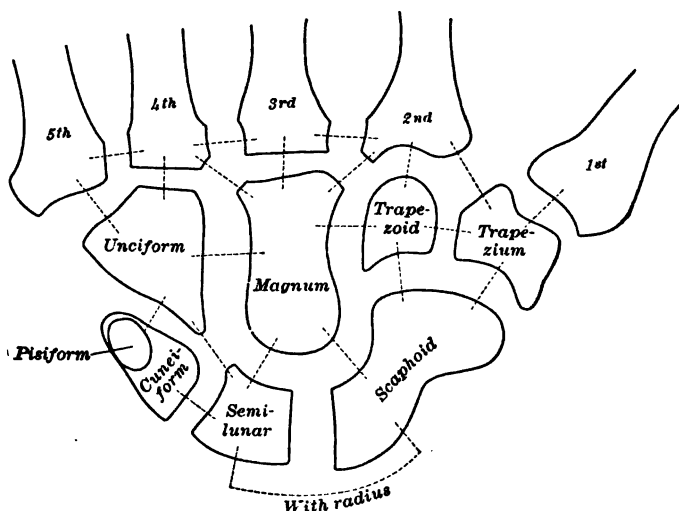

FIG. 152.—Diagram to show articulations.

Bones of the Upper Row.—The **scaphoid** or **navicular bone** (*os naviculare manus*) (Fig. 153) is the largest bone of the first row. It is situated at the upper and outer part of the carpus, its long axis being from above downward, outward, and forward.

FIG. 153.—The left scaphoid. A, seen from behind; B, seen from in front.

Surfaces.—The **superior surface** is convex, smooth, of triangular shape, and articulates with the lower end of the radius. The **inferior surface**, directed downward, outward, and backward, is smooth, convex, also triangular, and divided by a slight ridge into two parts, the external of which articulates with the trapezium, the inner with the trapezoid. The **posterior** or **dorsal surface** presents a narrow, rough groove which runs the entire length of the bone and serves for the attachment of ligaments. The **anterior** or **palmar surface** is concave above, and elevated at its lower and outer part into a prominent rounded **tuberosity** (*tuberculum ossis navicularis*), which projects forward from the front of the carpus and gives attach-

ment to the anterior annular ligament of the wrist and sometimes a few fibres of the Abductor pollicis. The **external surface** is rough and narrow, and gives attachment to the external lateral ligament of the wrist. The **internal surface** presents two articular facets; of these, the superior or smaller one is flattened, of semilunar form, and articulates with the semilunar; the inferior or larger is concave, forming, with the semilunar bone, a concavity for the head of the os magnum.

To ascertain to which side the bone belongs, hold the convex radial articular surface upward, and the dorsal surface backward; the prominent tubercle will be directed to the side to which the bone belongs.

Articulations.—With *five* bones—the radius above, trapezium and trapezoid below, os magnum and semilunar internally.

Attachment of Muscles.—Occasionally a few fibres of the Abductor pollicis.

The **semilunar** bone (Fig. 154) may be distinguished by its deep concavity and crescentic outline. It is situated in the centre of the upper row of the carpus, between the scaphoid and cuneiform.

FIG. 154.—The left semilunar. A, anterior and internal surfaces; B, external surface.

Surfaces.—The **superior surface**, convex, smooth, and bounded by four edges, articulates with the radius. The **inferior surface** is deeply concave, and of greater extent from before backward than transversely; it articulates with the head of the os magnum and by a long, narrow facet (separated by a ridge from the general surface) with the unciform bone. The **anterior or palmar** and **posterior or dorsal surfaces** are rough, for the attachment of ligaments, the former being the broader and of a somewhat rounded form. The **external surface** presents a narrow, flattened, semilunar facet for articulation with the scaphoid. The **internal surface** is marked by a smooth, quadrilateral facet, for articulation with the cuneiform.

To ascertain to which hand this bone belongs, hold it with the dorsal surface upward, and the convex articular surface backward; the quadrilateral articular facet will then point to the side to which the bone belongs.

Articulations.—With *five* bones—the radius above, os magnum and unciform below, scaphoid externally, and cuneiform internally.

The **cuneiform** (*os triquetrum*) (Fig. 155) may be distinguished by its pyramidal shape, and by its having an oval, isolated facet for articulation with the pisiform bone. It is situated at the upper and inner side of the carpus.

Surfaces.—The **superior surface** presents an internal, rough, nonarticular portion, and an external or articular portion, which is convex, smooth, and articulates with the triangular intra-articular fibrocartilage of the wrist. The **inferior surface**, directed outward, is concave, sinuously curved, and smooth for articulation with the unciform. The **posterior or dorsal surface** is

FIG. 155.—The left cuneiform, showing palmar and lateral surfaces.

rough, for the attachment of ligaments. The **anterior** or **palmar surface** presents, at its inner side, an oval facet, for articulation with the pisiform, and is rough externally, for ligamentous attachment. The **external surface**, the base of the pyramid, is marked by a flat, quadrilateral, smooth facet, for articulation with the semilunar. The **internal surface**, the summit of the pyramid, is pointed and roughened, for the attachment of the internal lateral ligament of the wrist.

To ascertain to which hand this bone belongs, hold it so that the base is directed backward, and the articular facet for the pisiform bone upward; the concave articular facet will point to the side to which the bone belongs.

Articulations.—With *three* bones—the semilunar externally, the pisiform in front, the unciform below; and with the triangular, interarticular fibrocartilage which separates it from the lower end of the ulna.

The **pisiform** (*os pisiforme*) (Fig. 156) may be known by its small size and by its presenting a single articular facet. It is situated on a plane anterior to the other bones of the carpus; it is spheroidal in form, with its long diameter directed vertically.

For cuneiform

FIG. 156.—The left pisiform, showing posterior and lateral surfaces.

Surfaces.—Its **posterior surface** is a smooth, oval facet, for articulation with the cuneiform. This facet approaches the superior, but not the inferior border of the bone. The **anterior** or **palmar surface** is rounded and rough, and gives attachment to the anterior annular ligament and to the Flexor carpi ulnaris and origin to the Abductor minimi digiti. The **outer** and **inner surfaces** are also rough, the former being concave, the latter usually convex.

To ascertain to which hand this bone belongs, hold the bone with its posterior or articular facet downward and the nonarticular portion of the same surface backward; the inner concave surface will point to the side to which it belongs.

Articulations.—With *one* bone, the cuneiform.

Attachment of Muscles.—To *two*—the Flexor carpi ulnaris and Abductor minimi digiti; and to the anterior annular ligament.

Bones of the Lower Row.—The **trapezium** (*os multangulum manus*) (Fig. 157) is of very irregular form. It may be distinguished by a deep groove, for the tendon of the Flexor carpi radialis muscle. It is situated at the external and inferior part of the carpus between the scaphoid and first metacarpal bone.

FIG. 157.—The left trapezium. A, as seen from in front; B, from above and mesal side.

Surfaces.—The **superior surface**, concave and smooth, is directed upward and inward, and articulates with the scaphoid. The **inferior surface**, directed downward and inward, is oval, concave from side to side, convex from before backward, so as to form a saddle-shaped surface, for articulation with the base of the first metacarpal bone. The **anterior** or **palmar surface** is narrow and rough. At its upper part is a deep groove running from above obliquely downward and inward; it transmits the tendon of the Flexor carpi radialis, and is bounded externally

by a prominent ridge, the **oblique ridge of the trapezium** (*tuberculum ossis multanguli majoris*). This surface gives origin to the Abductor pollicis, Opponens pollicis, deep head of the Flexor brevis pollicis muscles, and the anterior annular ligament. The **posterior or dorsal surface** is rough. The **external surface** is also broad and rough, for the attachment of ligaments. The **internal surface** presents two articular facets; the upper one, large and concave, articulates with the trapezoid; the lower one, small and oval, with the base of the second metacarpal bone.

To ascertain to which hand this bone belongs, hold it with the grooved palmar surface upward, and the external broad, nonarticular surface backward; the saddle-shaped surface will then be directed to the side to which the bone belongs.

Articulations.—With four bones—the scaphoid above, the trapezoid and second metacarpal bones internally, the first metacarpal below.

Attachment of Muscles.—Abductor pollicis, Opponens pollicis, and deep head of the Flexor brevis pollicis.

The **trapezoid** (*os multangulum minus*) (Fig. 158) is the smallest bone in the second row. It may be known by its wedge-shaped form, the broad end of the wedge forming the dorsal, the narrow end the palmar, surface, and by its having four articular surfaces touching each other and separated by sharp edges.

FIG. 158.—The left trapezoid. A, as seen from above, inner side and behind; B, from in front, below and outer side.

Surfaces.—The **superior surface**, quadrilateral in form, smooth, and slightly concave, articulates with the scaphoid. The **inferior surface** articulates with the upper end of the second metacarpal bone; it is convex from side to side, concave from before backward, and subdivided by an elevated ridge into two unequal lateral facets. The **posterior or dorsal** and **anterior or palmar surfaces** are rough, for the attachment of ligaments, the former being the larger of the two. The **anterior surface** gives origin to the deep head of the Flexor brevis pollicis. The **external surface**, convex and smooth, articulates with the trapezium. The **internal surface** is concave and smooth in front, for articulation with the os magnum; rough behind, for the attachment of an interosseous ligament.

To ascertain to which hand this bone belongs, let the broad dorsal surface be held upward, and the inferior concavo-convex surface forward; the internal concave surface will then point to the side to which the bone belongs.

Articulations.—With four bones—the scaphoid above, second metacarpal bone below, trapezium externally, os magnum internally.

Attachment of Muscles.—To the deep head of the Flexor brevis pollicis.

The **os magnum** (*os capitatum*) (Fig. 159) is the largest bone of the carpus, and occupies the centre of the wrist. It presents, above, a rounded portion or **head**, which is received into the concavity formed by the scaphoid and semilunar bones; a constricted portion or **neck**; and, below, the **body**.

Surfaces.—The **superior surface** is rounded, smooth, and articulates with the semilunar. The **inferior surface** is divided by two ridges into three facets for articulation with the second, third, and fourth metacarpal bones, that for the third (the

middle facet) being the largest of the three. The **posterior** or **dorsal surface** is broad and rough; the **anterior** or **palmar**, narrow, rounded, and also rough, for the attachment of ligaments, and it gives origin to a part of the Adductor obliquus pollicis and to the deep head of the Flexor brevis pollicis. The **external surface** articulates with the trapezoid by a small facet at its anterior inferior angle, behind which is a rough depression for the attachment of an interosseous ligament.

FIG. 159.—The left os magnum. A, outer side seen from below; B, internal posterior surface.

Above this is a deep and rough groove, which forms part of the neck and serves for the attachment of ligaments, bounded superiorly by a smooth, convex surface for articulation with the scaphoid. The **internal surface** articulates with the unciform by a smooth, concave, oblong facet which occupies its posterior and superior parts, and is rough in front, for the attachment of an interosseous ligament.

To ascertain to which hand this bone belongs, the rounded head should be held upward, and the broad dorsal surface forward; the internal concave articular surface will point to the side to which the bone belongs.

Articulations.—With *seven* bones—the scaphoid and semilunar above; the second, third, and fourth metacarpal below; the trapezoid on the radial side; and the unciform on the ulnar side.

Attachment of Muscles.—Part of the Adductor obliquus pollicis and the deep head of the Flexor brevis pollicis.

The **unciform** (*os hamatum*) (Fig. 160) may be readily distinguished by its wedge-shaped form and the hook-like process that projects from its palmar surface. It is situated at the inner and lower angle of the carpus, with its **base** downward, resting on the two inner metacarpal bones, and its **apex** directed upward and outward.

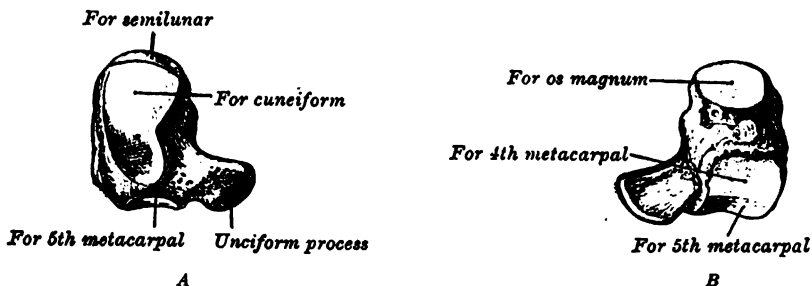

FIG. 160.—The left unciform. A, internal surface; B, outer and distal surfaces.

Surfaces.—The **superior surface**, the apex of the wedge, is narrow, convex, smooth, and articulates with the semilunar. The **inferior surface** articulates with the fourth and fifth metacarpal bones, the concave surface for each being separated by a ridge which runs from before backward. The **posterior** or **dorsal**

surface is triangular and rough, for ligamentous attachment. The **anterior** or **palmar surface** presents, at its lower and inner side, a curved, hook-like process of bone, the **unciform process** (*hamulus ossis hamati*), directed from the palmar surface forward and outward. It gives attachment by its apex to the annular ligament and insertion to the Flexor carpi ulnaris; by its inner surface it gives origin to the Flexor brevis minimi digiti and the Opponens minimi digiti; and is grooved on its outer side, for the passage of the Flexor tendons into the palm of the hand. This is one of the four eminences on the front of the carpus to which the anterior annular ligament is attached, the others being the pisiform internally, the oblique ridge of the trapezium and the tuberosity of the scaphoid externally. The **internal surface** articulates with the cuneiform by an oblong facet cut obliquely from above, downward and inward. The **external surface** articulates with the os magnum by its upper and posterior part, the remaining portion being rough, for the attachment of ligaments.

To ascertain to which hand it belongs, hold the apex of the bone upward, and the broad dorsal surface backward; the concavity of the process will be on the side to which the bone belongs.

Articulations.—With *five* bones—the semilunar above, the fourth and fifth metacarpal below, the cuneiform internally, the os magnum externally.

Attachment of Muscles.—To *three*—the Flexor brevis minimi digiti, the Opponens minimi digiti, the Flexor carpi ulnaris.

The Metacarpus (Ossa Metacarpalia) (Figs. 150, 151).

The **metacarpal bones** are *five* in number, and they are numbered from 1 to 5 inclusive, the first being the metacarpal bone of the thumb, the fifth the metacarpal bone of the little finger. They are long, cylindrical bones, presenting for examination a shaft and two extremities.

Common Characters of the Metacarpal Bones.—The **shaft** (*corpus*) is prismatic in form, and curved longitudinally, so as to be convex in the longitudinal direction behind, concave in front. It presents three surfaces—two lateral and one posterior. The two lateral surfaces constitute the **palmar** or **volar aspect**. The **lateral surfaces** are concave, for the origin of the Interossei muscles, and separated from one another by a prominent anterior ridge. The **posterior** or **dorsal surface** presents in its distal half a smooth, triangular, flattened area which is covered, in the recent state, by the tendons of the Extensor muscles. This triangular surface is bounded by two lines, which commence in small tubercles situated on the dorsal aspect on either side of the digital extremity, and, running backward, converge to meet some distance behind the centre of the bone and form a ridge which runs along the rest of the dorsal surface to the carpal extremity. This ridge separates two lateral, sloping surfaces for the origin of the Dorsal interossei muscles.¹ To the tubercles on the digital extremities are attached the lateral ligaments of the metacarpophalangeal joints. On the palmar surface of each metacarpal bone is a **nutrient foramen**, which opens into a **nutrient canal**. In the first metacarpal the direction of this foramen is toward the phalanges (distad). In each of the other metacarpals it is from the phalanges (proximad).

The **carpal** or **proximal extremity** or **base** (*basis*) is of a cuboidal form, and broader behind than in front; it articulates above with the carpus, and on each side with the adjoining metacarpal bones; its **dorsal** and **palmar surfaces** are rough, for the attachment of tendons and ligaments.

The **distal extremity**, or **head** (*capitulum*), presents an oblong surface, markedly

¹ By these sloping surfaces the metacarpal bones of the hand may be at once differentiated from the metatarsal bones of the foot.

convex from before backward, less so from side to side, and flattened laterally; it articulates with the proximal phalanx; it is broader and extends farther forward on the palmar than on the dorsal aspect. It is longer in the antero-posterior than in the transverse diameter. On either side of the head is a tubercle for the attachment of the lateral ligament of the metacarpophalangeal joint. The **posterior surface**, broad and flat, supports the Extensor tendons; the **anterior surface** is grooved in the middle line for the passage of the Flexor tendons, and marked on each side by an articular eminence continuous with the terminal articular surface.

The **metacarpal spaces** (*spatia interossea metacarpi*) are the intervals between the metacarpal bones. They are occupied by the Interossei muscles. The broadest space is between the metacarpal bones of the thumb and index finger.

Peculiar Characters of the Metacarpal Bones.

—The **metacarpal bone of the thumb** (*os metacarpale I*) (Fig. 161) is shorter and wider than the rest, diverges to a greater degree from the carpus, and its palmar surface is directed inward toward the palm. The **shaft** is flattened and broad on its dorsal aspect, and does not present the ridge which is found on the other metacarpal bones; it is concave from above downward, on its palmar surface. The **carpal extremity**, or **base**, presents a concavo-convex surface, for articulation with the trapezium; it has no lateral facets, but presents

FIG. 161.—The first metacarpal. (Left.)

externally a tubercle for the insertion of the Extensor ossis metacarpi pollicis. The **distal extremity** is less convex than that of the other metacarpal bones, broader from side to side than from before backward. It presents on its palmar aspect two distinct articular eminences for the two sesamoid bones in the tendons of the Flexor brevis pollicis, the outer one being the larger of the two.

The side to which this bone belongs may be known by holding it in the position it occupies in the hand, with the carpal extremity upward and the dorsal surface backward; the tubercle for the Extensor ossis metacarpi pollicis will point to the side to which it belongs.

Attachment of Muscles.—To *four*—the Opponens pollicis, the Extensor ossis metacarpi pollicis, the Flexor brevis pollicis, and the First dorsal interosseous.

The **metacarpal bone of the index finger** (*os metacarpale II*) (Fig. 162) is the longest and its base the largest of the other four. Its **carpal extremity** is prolonged upward and inward, forming a prominent ridge. The dorsal and palmar surfaces of this extremity are rough, for the attachment of tendons and ligaments. It presents four articular facets—three on the upper aspect of the base; the middle one of the three is the largest, concave from side to side, convex from before backward, for articulation with the trapezoid; the external one is a small, flat, oval facet, for articulation with the trapezium; the internal one on the summit of the ridge is long and narrow, for articulation with the os magnum. The fourth facet is on the inner or the ulnar side of the extremity of the bone, and is for articulation with the third metacarpal bone.

The side to which this bone belongs is indicated by the absence of the lateral facet on the outer (radial) side of its base, so that if the bone is placed with the base toward the student and the palmar surface upward, the side on which there is no lateral facet will be that to which it belongs.

Attachment of Muscles.—To *six*—Flexor carpi radialis, Extensor carpi radialis longior, Abductor obliquus pollicis, First and Second dorsal interosseous, and First palmar interosseous.

The metacarpal bone of the middle finger (*os metacarpale III*) (Fig. 163) is a little smaller than the preceding; it presents a pyramidal eminence, the **styloid process** (*processus styloideus*), on the radial side of its base (dorsal aspect), which extends upward behind the *os magnum*; immediately below this, on the dorsal aspect, is a rough surface for the attachment of the *Extensor carpi radialis brevis*. The carpal, articular facet is concave behind, flat in front, and articulates with the *os magnum*. On the radial side is a smooth, concave facet, for articulation with the second metacarpal bone, and on the ulnar side two small, oval facets, for articulation with the fourth metacarpal.

The side to which this bone belongs is easily recognized by the styloid process on the radial side of its base. With the palmar surface uppermost and the base toward the student, this process points toward the side to which the bone belongs.

Attachment of Muscles.—To *six*—*Extensor carpi radialis brevis*, *Flexor carpi radialis*, *Adductor transversus pollicis*, *Adductor obliquus pollicis*, and *Second and Third dorsal interosseous*.

FIG. 162.—The second metacarpal. (Left.)

FIG. 163.—The third metacarpal. (Left.)

The metacarpal bone of the ring finger (*os metacarpale IV*) (Fig. 164) is shorter and smaller than the preceding, and its base small and quadrilateral; the carpal surface of the base presenting two facets, a large one internally, for articulation with the *unciform*, and a small one externally, for the *os magnum*. On the radial side are two oval facets, for articulation with the third metacarpal bone; and on the ulnar side a single concave facet, for the fifth metacarpal.

If this bone is placed with the base toward the student and the palmar surface upward, the radial side of the base, which has two facets for articulation with the third metacarpal bone, will be on the side to which it belongs. If, as sometimes happens in badly marked bones, one of these facets is indistinguishable, the side may be known by selecting the surface on which the larger articular facet is present. This facet is for the fifth metacarpal bone, and would therefore be situated on the ulnar side—that is, the one to which the bone does *not* belong.

Attachment of Muscles.—To *three*—the *Third and Fourth dorsal* and *Second palmar interosseous*.

The metacarpal bone of the little finger (*os metacarpale V*) (Fig. 165) presents on its base one facet, which is concavo-convex, and which articulates with the

unciform bone, and one lateral, articular facet, which articulates with the fourth metacarpal bone. On its ulnar side is a prominent tubercle, for the insertion of the tendon of the Extensor carpi ulnaris. The dorsal surface of the shaft is marked by an oblique ridge which extends from near the ulnar side of the upper extremity to the radial side of the lower. The outer division of this surface serves for the attachment of the Fourth dorsal interosseous muscle; the inner division is smooth and covered by the Extensor tendons of the little finger.

FIG. 164.—The fourth metacarpal. (Left.)

FIG. 165.—The fifth metacarpal. (Left.)

If this bone is placed with its base toward the student and its palmar surface upward, the side of the head which has a lateral facet will be that to which the bone belongs.

Attachment of Muscles.—To *five*—the Extensor carpi ulnaris, Flexor carpi ulnaris, Opponens minimi digiti, Fourth dorsal, and Third palmar interossei.

Articulations.—Besides the phalangeal articulations, the first metacarpal bone articulates with the trapezium; the second with the trapezium, trapezoid, os magnum, and third metacarpal bones; the third with the os magnum and second and fourth metacarpal bones; the fourth with the os magnum, unciform, and third and fifth metacarpal bones; and the fifth with the unciform and fourth metacarpal.

The *first* has no lateral facets on its carpal extremity; the *second* has no lateral facet on its radial side, but one on its ulnar side; the *third* has one on its radial and two on its ulnar side; the *fourth* has two on its radial and one on its ulnar side; and the *fifth* has only one on its radial side.

The Phalanges of the Hand (Phalanges Digitorum Manus).

The **phalanges** (*internodia; phalanges digitorum manus*) are *fourteen* in number, three for each finger, and two for the thumb. In numbering them the proximal bone is designated as the first phalanx (*phalanx I*). They are long bones, and present for examination a shaft and two extremities. The **shaft** (*corpus phalangis*) tapers from above downward, is convex posteriorly, concave in front from above downward, flat from side to side, and marked laterally by rough ridges, which give attachment to the fibrous sheaths of the Flexor tendons. A nutrient foramen on the palmar surface leads into a **nutrient canal** which runs toward the periphery (*distad*). The **metacarpal extremity**, or **base** (*basis phalangis*), of each phalanx in the first row presents an oval, concave, articular surface, broader from side to side than from before backward; and the same extremity

in the other two rows, a double concavity, separated by a longitudinal median ridge, extending from before backward. The **distal extremity** of the first phalanx of the thumb and of the first and second phalanx of each of the fingers is smaller than the base, and terminates in two small, lateral condyles, separated by a slight groove (*trochlea phalangis*); the articular surface being prolonged farther forward on the palmar than on the dorsal surface, especially in the first row.

The **ungual phalanges** (*distal*) are convex on their dorsal, flat on their palmar, surfaces; they are recognized by their small size and by a roughened, elevated surface of a horseshoe form on the palmar aspect of their unguinal extremity (*tuberositas unguicularis*), which serves to support the sensitive pulp of the finger.

Articulations.—The first row, with the metacarpal bones and the second row of phalanges; the second row, with the first and third; the third, with the second row.

Attachment of Muscles.—To the base of the first phalanx of the thumb, *five* muscles—the Extensor brevis pollicis, Flexor brevis pollicis, Adductor pollicis, Adductores transversus and Obliquus pollicis. To the second phalanx, *two*—the Flexor longus pollicis and the Extensor longus pollicis. To the base of the first phalanx of the index finger, the First dorsal and the First palmar interosseous; to that of the middle finger, the Second and Third dorsal interosseous; to that of the ring finger, the Fourth dorsal and the Second palmar interossei; and to that of the little finger, the Third palmar interosseous, the Flexor brevis minimi digiti, and Abductor minimi digiti. To the second phalanges, the Flexor sublimis digitorum, Extensor communis digitorum, and; in addition, the Extensor indicis to the index finger, the Extensor minimi digiti to the little finger. To the third phalanges, the Flexor profundus digitorum and Extensor communis digitorum.

Surface Form of Carpal and Metacarpal Bones and of the Phalanges.—On the front of the wrist are two subcutaneous eminences, one on the radial side, the larger and flatter, due to the tuberosity of the scaphoid and the ridge on the trapezium; the other, on the ulnar side, caused by the pisiform bone. The tubercle of the scaphoid may be felt just below and in front of the apex of the styloid process of the radius. It is best perceived by extending the hand on the forearm. Immediately below may be felt another prominence, better marked than the tubercle; this is the ridge on the trapezium which gives attachment to some of the short muscles of the thumb. On the inner side of the front of the wrist the pisiform bone may be felt, forming a small but prominent projection in this situation. It is some distance below the styloid process of the ulna, and may be said to be just below the level of the styloid process of the radius. The rest of the front of the carpus is covered by tendons and the annular ligament, and entirely concealed, with the exception of the hooked process of the unciform, which can only be made out with difficulty. The back of the carpus is convex and covered by the Extensor tendons, so that none of the posterior surfaces of the bones are to be felt, with the exception of the cuneiform on the inner side. Below the carpus the dorsal surfaces of the metacarpal bones, except the fifth, are covered by tendons, and are scarcely visible except in very thin hands. The dorsal surface of the fifth is, however, subcutaneous throughout almost its whole length, and may be plainly perceived and felt. In addition to this, slightly external to the middle line of the hand, is a prominence, frequently well marked, but occasionally indistinct, formed by the base of the metacarpal of the middle finger. The heads of the metacarpal bones may be plainly felt and seen, rounded in contour and standing out in bold relief under the skin, when the fist is clenched. It should be borne in mind that when the fingers are flexed on the hand, the articular surfaces of the first phalanges glide off the heads of the metacarpal bones on to their anterior surfaces, so that the head of these bones form the prominence of the knuckles and receive the force of any blow which may be given. The head of the third metacarpal bone is the most prominent, and receives the greater part of the shock of the blow. This bone articulates with the os magnum, so that the concussion is carried through this bone to the scaphoid and semilunar, with which the head of the os magnum articulates, and by these bones is transferred to the radius, along which it may be carried to the capitellum of the humerus. The enlarged extremities of the phalanges may be plainly felt; they form the joints of the fingers. When the digits are bent the proximal phalanges of the joints form prominences, which in the joint between the first and second phalanges is slightly hollowed, in accordance with the grooved shape of their articular surfaces, while at the last row the prominence is flattened and square-shaped. In the palm of the hand the four inner metacarpal bones are covered by muscles, tendons, and the palmar fascia, and no part of them but their heads is to be distinguished. With regard to the thumb, on the dorsal aspect the base of the metacarpal bone forms a prominence below the styloid process of the radius; the shaft is to be felt, covered by tendons, terminating at its head in a flattened prominence, in front of which can be felt the sesamoid bones.

Applied Anatomy.—The carpal bones are not very liable to *fracture*, except from extreme violence, when the parts may be so comminuted as to necessitate amputation. Occasionally

they are the seat of *tuberculous* disease. The metacarpal bones and the phalanges are not infrequently broken by direct violence. The first metacarpal bone is the one most commonly fractured; then the second, the fourth, and the fifth, the third being the one least frequently broken. There are two diseases of the metacarpal bones and phalanges which require special mention on account of the frequency of their occurrence. One is *tuberculous dactylitis*, consisting in a deposit of tuberculous material in the medullary canal, expanding the bone, with subsequent caseation and resulting necrosis. The other is *chondroma*, which is perhaps more frequently found in connection with the metacarpal bones and phalanges than with any other bones. When chondromatous growth takes place there are usually multiple tumors, and they may spring either from the medullary canal or from the periosteum.

Development of the Bones of the Hand.—The carpal bones are each developed from a single centre. At birth they are all cartilaginous. Ossification proceeds in the following order (Fig. 166): In the os magnum and unciform an ossific point appears during the first year, the former preceding the latter; in the cuneiform, at the third year; in the trapezium and semilunar, at the fifth year, the latter preceding the former; in the scaphoid, in the sixth to the eighth year; in the trapezoid, during the eighth year; and in the pisiform, about the twelfth year.

FIG. 166.—Plan of the development of the bones of the hand.

Occasionally an additional bone, the *os centrale*, is found in the carpus, lying between the scaphoid, trapezoid, and os magnum. During the second month of fetal life it is represented by a small cartilaginous nodule, which, however, fuses with the cartilaginous scaphoid about the third month. Sometimes the styloid process of the third metacarpal is detached and forms an additional ossicle.

The **metacarpal bones** are each developed from *two* centres, *one* for the shaft and *one* for the distal extremity for the four inner metacarpal bones; *one* for the shaft and *one* for the base for the metacarpal bone of the thumb, which in this respect resembles the phalanges.¹ Ossi-

¹ Allan Thomson has demonstrated the fact that the first metacarpal bone is often developed from three centres; that is to say, there is a separate nucleus for the distal end, forming a distinct epiphysis, visible at the age of seven or eight years. He also states that there are traces of a proximal epiphysis in the second metacarpal bone.—*Journal of Anatomy and Physiology*, 1869.

fication commences in the centre of the shaft about the eighth or ninth week, the centre for the first metacarpal bone being the last to appear; ossification gradually proceeds to either end of the bone: about the third year the distal extremities of the four inner metacarpal bones and the base of the first metacarpal begin to ossify, and they unite with the shaft about the twentieth year.

The *phalanges* are each developed from *two* centres, *one* for the shaft and *one* for the base. Ossification commences in the shaft, in all three rows, at about the eighth week, and gradually involves the whole bone excepting the upper extremity. Ossification of the base commences in the first row between the third and fourth years, and a year later in those of the second and third rows. The two centres become united, in each row, between the eighteenth and twentieth years.

In the ungual phalanges the centre for the shaft appears at the distal extremity of the phalanx, instead of at the middle of the shaft, as is the case with the other phalanges. The ungual phalanges are the first bones of the hands to begin to ossify.

THE LOWER EXTREMITY.

The *lower extremity* consists of the following bones: Ossa innominata (with the sacrum and coccyx forming the *pelvis*), the femur (*thigh*), the tibia and fibula (the *leg*), the tarsus, the metatarsus and phalanges (the *foot*).

THE OS INNOMINATUM, CALLED ALSO OS COXAE, HIP BONE (Figs. 167, 168).

The *os innominatum* is so called from bearing no resemblance to any known object. It is a large, irregularly shaped, flat bone, constricted in the centre and expanded above and below. With its fellow of the opposite side it forms the sides and anterior wall of the pelvic cavity. In young subjects it consists of three separate parts, which meet and form the large, cup-like cavity, the *acetabulum*, situated near the middle of the outer surface of the bone; and, although in the adult these have become united, it is usual to describe the bone as divisible into three portions—the *ilium*, the *ischium*, and the *pubis*.

The *ilium* is the superior, broad, and expanded portion which runs upward from the acetabulum and forms the prominence of the hip.

The *ischium* is the inferior and strongest portion of the bone; it proceeds downward from the acetabulum, expands into a large tuberosity, and then, curving forward, forms, with the descending ramus of the os pubis, a large aperture, the obturator foramen.

The *os pubis* is that portion which extends inward and downward from the acetabulum to articulate in the middle line with the bone of the opposite side; it forms the front of the pelvis and supports the external organs of generation.

The *ilium* (*os ilium*) presents for examination two surfaces, an external and an internal, a crest, and two borders, an anterior and a posterior.

The *external surface* (Fig. 167) is divided into two parts—an upper or gluteal and a lower or acetabular. The upper portion—known as the *dorsum ilii*—is directed backward and outward behind, and downward and outward in front. It is smooth, convex in *front*, deeply concave *behind*; bounded *above* by the crest, *below* by the upper border of the acetabulum; in *front* and *behind* by the anterior and posterior borders. This surface is crossed in an arched direction by three semicircular lines—the superior, middle, and inferior curved lines. The *superior curved line* (*linea glutea posterior*), the shortest of the three, commences at the crest, about two inches in front of its posterior extremity; it is at first distinctly marked, but as it passes downward and backward to the upper part of the great sacrosciatic notch, where it terminates, it becomes less marked, and is often altogether lost. Behind this line is a narrow semilunar surface, the upper part of which is rough and affords origin to part of the Gluteus maximus; the lower part is smooth and has no muscle fibres attached to it. The *middle curved line* (*linea*

to the upper part of the acetabulum, is a roughened surface (sometimes a depression), from which arises the reflected tendon of the Rectus femoris muscle.

The lower or acetabular part of the external surface enters into the formation of the acetabulum, of which it forms rather less than two-fifths. It is separated from the gluteal portion by a prominent rim, which forms part of the margin of the acetabular cavity.

FIG. 168.—Right os innominatum. Internal surface.

The **internal surface** (Fig. 168) is bounded *above* by the crest; *below* it is continuous with the pelvic surface of the os pubis and ischium, a faint line only indicating the place of union; and *before* and *behind* it is bounded by the anterior and posterior borders. It presents a large, smooth, concave surface, called the **iliac fossa** (*fossa iliaca*), which lodges the Iliacus muscle, and presents at its lower part the orifice of a nutrient canal, and below this a smooth, rounded border, the **iliopectinal line** (*linea arcuata*), which separates the iliac fossa from that

portion of the internal surface which enters into the formation of the true pelvis, and which gives origin to part of the Obturator internus muscle. Behind the iliac fossa is a rough surface divided into two portions, an anterior and a posterior. The **anterior** (*facies auricularis*), so called from its resemblance in shape to the ear, is coated with cartilage in the recent state, and articulates with a surface of similar shape on the side of the sacrum. The **posterior portion** (*tuberositas iliaca*) is rough, for the attachment of the posterior sacroiliac ligaments and for a part of the origin of the Erector and Multifidus spinæ.

The **crest of the ilium** (*crista iliaca*) is convex in its general outline and sinuously curved, being concave inward in front, concave outward behind. It is longer in the female than in the male, very thick behind, and thinner at the centre than at the extremities. It terminates at either end in a prominent eminence, the **anterior superior** and **posterior superior spinous process** (*spina iliaca anterior superior et spina iliaca posterior superior*). The surface of the crest is broad, and divided into an **external lip** (*labium externum*), an **internal lip** (*labium internum*), and an **intermediate space** (*linea intermedia*). About two inches behind the anterior superior spinous process there is a prominent **tubercle** on the outer lip. To the external lip is attached the Tensor fasciæ femoris, Obliquus externus abdominis, and Latissimus dorsi, and along its whole length, the fascia lata; to the space between the lips, the Internal oblique; to the internal lip, the Transversalis, Quadratus lumborum, and Erector spinæ, the Iliacus, and the iliac fascia.

The **anterior border** of the ilium is concave. It presents two projections, separated by a notch. Of these, the uppermost, situated at the junction of the crest and anterior border, is called the **anterior superior spinous process of the ilium**, the outer border of which gives attachment to the fascia lata and the origin of the Tensor fasciæ femoris; its inner border, to the Iliacus; while its extremity affords attachment to Poupert's ligament and the origin of the Sartorius. Beneath this eminence is a notch which gives origin to the Sartorius muscle, and across which passes the external cutaneous nerve. Below the notch is the **anterior inferior spinous process**, which terminates in the upper lip of the acetabulum; it gives origin to the straight tendon of the Rectus femoris muscle and the ilio-femoral ligament. On the inner side of the anterior inferior spinous process is a broad, shallow groove, over which passes the Iliopsoas muscle. This groove is bounded internally by an eminence, the **iliopectineal eminence** (*eminentia iliopectinea*), which marks the point of union of the ilium and os pubis.

The **posterior border** of the ilium, shorter than the anterior, also presents two projections separated by a notch, the **posterior superior spinous process** (*spina iliaca posterior superior*) and the **posterior inferior spinous process** (*spina iliaca posterior inferior*). The former corresponds with that portion of the inner surface of the ilium which serves for the attachment of the oblique portion of the sacroiliac ligaments and the Multifidus spinæ muscle; the latter, to the auricular portion which articulates with the sacrum. Below the posterior inferior spinous process the posterior border forms the upper part of a deep notch, the **great sacrosciatic notch** (*incisura ischiadica major*).

The **Ischium** (*os ischii*) forms the lower and back part of the os innominatum. It is divisible into a thick and solid portion—the body; a large, rough eminence, on which the trunk rests in sitting—the tuberosity; and a thin part which passes forward and slightly upward—the ramus.

The **body** (*corpus ossis ischii*), somewhat triangular in form, presents three surfaces, external, internal, and posterior; and three borders, external, internal, and posterior. The **external surface** corresponds to that portion of the acetabulum formed by the ischium; it is smooth and concave, and forms a little more than two-fifths of the acetabular cavity; its outer margin is bounded by a prominent rim or lip, the external border, to which the cotyloid fibrocartilage is attached.

Below the acetabulum, between it and the tuberosity, is a deep groove, along which the tendon of the Obturator externus muscle runs as it passes outward to be inserted into the digital fossa of the femur. The **internal surface** is smooth, concave, and enters into the formation of the lateral boundary of the true pelvic cavity. This surface is perforated by two or three large, vascular foramina, and affords origin to part of the Obturator internus muscle. The **posterior surface** is quadrilateral in form, broad and smooth. Below, where it joins the tuberosity, it presents a groove, the **obturator groove** (*sulcus obturatorius*), continuous with that on the external surface; in this groove is received the posterior fleshy part of the Obturator externus muscle when the thigh is flexed. The lower edge of this groove is formed by the tuberosity of the ischium, and affords origin to the Gemellus inferior muscle. The posterior surface is limited, externally, by the margin of the acetabulum; behind, by the posterior border; it supports the Piriformis, the two Gemelli, and the Obturator internus muscles in their passage outward to the great trochanter. The **external border** forms the prominent rim of the acetabulum, and separates the posterior from the external surface. To it is attached the cotyloid fibrocartilage. The **internal border** is thin, and forms the outer circumference of the obturator foramen. The **posterior border** of the body of the ischium is continuous with the posterior border of the ilium; it presents, a little below the centre, a thin and pointed, triangular eminence, the **spine of the ischium** (*spina ischiadica*), more or less elongated in different subjects; its external surface gives origin to the Gemellus superior, its internal surface to the Coccygeus and Levator ani; while to the pointed extremity is connected the lesser sacrosclatic ligament. Above the spine is a notch of large size, the **great sacrosclatic notch**, converted into a foramen, the **great sacrosclatic foramen** (*foramen ischiadicum majus*), by the lesser and greater sacrosclatic ligaments; it transmits the Piriformis muscle, the gluteal vessels, and superior and inferior gluteal nerves; the sciatic vessels, the greater and lesser sciatic nerves, the internal pudic vessels and nerve, and the nerves to the Obturator internus and Quadratus femoris. Of these, the gluteal vessels and superior gluteal nerve pass out above the Piriformis muscle, the other structures, below it. Below the spine is a smaller notch, the **lesser sacrosclatic notch** (*incisura ischiadica minor*); it is smooth, coated in the recent state with cartilage. It is converted into a foramen, the **lesser sacrosclatic foramen** (*foramen ischiadicum minus*), by the sacrosclatic ligaments, and transmits the tendon of the Obturator internus, the nerve which supplies that muscle, and the internal pudic vessels and nerve.

The **tuberosity of the ischium** (*tuber ischiadicum*) is the portion of bone between the body and the ascending ramus. The tuberosity presents for examination three surfaces—external, internal, and posterior. The **external surface** is quadrilateral in shape, and rough for the attachment of muscles. It is bounded *above* by the groove for the tendon of the Obturator externus; in *front* it is limited by the posterior margin of the obturator foramen, and *below* it is continuous with the ramus of the bone; *behind*, it is bounded by a prominent margin which separates it from the posterior surface. In front of this margin the surface gives origin to the Quadratus femoris, and anterior to this some of the fibres of origin of the Adductor magnus. The **internal surface** forms part of the bony wall of the true pelvis. In *front* it is limited by the posterior margin of the obturator foramen; *behind*, it is bounded by a sharp ridge, for the attachment of a falciform prolongation of the great sacrosclatic ligament; it sometimes presents a groove on the inner side of this ridge for the lodgement of the internal pudic vessels and nerve; and, more anteriorly, has attached the Transversus perinaei and Erector penis vel clitoridis muscles. The **posterior surface** is divided into two portions—a lower rough, somewhat triangular part, and an upper smooth, quadrilateral portion.

The anterior portion is subdivided by a prominent vertical ridge, passing from base to apex, into two parts; the outer one gives origin to the Adductor magnus; the inner, to the great sacrosciatic ligament. The upper portion is subdivided into two facets by an oblique ridge which runs downward and outward; from the upper and outer facet arises the Semimembranosus; from the lower and inner, the Biceps and Semitendinosus.

The **ramus** or **inferior ramus** or **ascending ramus of the ischium** (*ramus inferior ossis ischii*) is the thin, flattened part of the ischium which ascends from the tuberosity upward and inward, and joins the descending ramus of the os pubis, their point of junction being indicated in the adult by a rough line. The outer surface of the ramus is rough, for the origin of the Obturator externus muscle, and also some fibres of the Adductor magnus; its inner surface forms part of the anterior wall of the pelvis. Its inner border is thick, rough, slightly everted, forms part of the outlet of the pelvis, and presents two ridges and an intervening space. The ridges are continuous with similar ones on the descending ramus of the os pubis; to the outer one is attached the deep layer of the superficial perineal fascia, and to the inner, the superficial layer of the triangular ligament of the perineum. If these two ridges are traced downward, they will be found to join with each other just behind the point of origin of the Transversus perinei muscle; here the two layers of fascia are continuous behind the posterior border of the muscle. To the intervening space, just in front of the point of junction of the ridges, is attached the Transversus perinaei muscle, and in front of this arises a portion of the crus penis vel clitoridis and the Erector penis vel clitoridis muscle. Its outer border is thin and sharp, and forms part of the inner margin of the obturator foramen.

The **Pubis** (*os pubis*) forms the anterior part of the os innominatum, and, with the bone of the opposite side, forms the front boundary of the true pelvic cavity. It is divisible into a body, a superior or ascending and an inferior or descending ramus.

The **body** (*corpus ossis pubis*) is the broad portion of bone formed by the junction of the two rami. It is somewhat quadrilateral in shape, and presents for examination two surfaces and three borders. The **anterior surface** is rough, directed downward and outward, and serves for the attachment of various muscles. From the upper and inner angle, immediately below the upper border, arises the Adductor longus; lower down, from without inward, arise the Obturator externus, the Adductor brevis, and the upper part of the Gracilis. The **posterior surface**, convex from above downward, concave from side to side, is smooth, and forms part of the anterior wall of the pelvis. It gives origin to the Levator ani, Obturator internus, a few muscle fibres prolonged from the bladder, and the puboprostatic ligaments. At the outer part of the **upper border** is a prominent tubercle, which projects forward and is called the **spine** (*tuberculum pubicum*); to it is attached Poupart's ligament. Passing upward and outward from this is a prominent ridge, forming part of the **iliopectineal line** (*linea arcuata*). It marks the brim of the true pelvis; to it are attached a portion of the conjoined tendon of the Internal oblique and Transversalis muscles, Gimbernat's ligament, and the triangular fascia of the abdomen. Internal to the spine the upper border is called the **crest**, which extends from this process to the inner extremity of the bone. It affords attachment to the conjoined tendon of the Internal oblique and Transversalis, and to the Rectus abdominis and Pyramidalis muscles. The point of junction of the crest with the inner border of the bone (symphysis) is called the **angle**; to it, as well as to the symphysis, is attached the internal pillar of the external abdominal ring. The **internal border** is articular; it is oval, covered by eight or nine transverse ridges, or a series of nipple-like processes arranged in rows, separated by grooves; they serve for the attachment of a thin layer of cartilage, placed between it and the central fibrocartilage. The **outer border** presents a

sharp margin, which forms part of the circumference of the obturator foramen and affords attachment to the obturator membrane.

The **ascending or superior ramus of the pubis** (*ramus superior ossis pubis*) extends from the body to the point of junction of the os pubis with the ilium, and forms the upper part of the circumference of the obturator foramen. It presents for examination a superior, inferior, and posterior surface, and an outer extremity. The **superior surface** presents a continuation of the iliopectineal line, already mentioned as commencing at the pubic spine. In front of this ridge the surface of bone is triangular in form, wider externally than internally, smooth, and is covered by the Pectineus muscle. The surface is bounded externally by a rough eminence, the **iliopectineal eminence** (*eminentia iliopectinea*), which serves to indicate the point of junction of the ilium and os pubis, and gives attachment to the Psoas parvus, when this muscle is present. The triangular surface is bounded below by a prominent ridge, the **obturator crest** (*crista obturatoria*), which extends from the cotyloid notch to the spine of the os pubis. The **inferior surface** forms the upper boundary of the obturator foramen, and presents externally a broad and deep oblique groove, the **obturator groove** (*sulcus obturatorius*), for the passage of the obturator vessels and nerve; and internally a sharp margin which forms part of the circumference of the obturator foramen, and to which the obturator membrane is attached. The **posterior surface** forms part of the anterior boundary of the true pelvis. It is smooth, convex from above downward, and affords origin to some fibres of the Obturator internus. The **outer extremity**, the thickest part of the ramus, forms one-fifth of the cavity of the acetabulum.

The **descending or inferior ramus of the pubis** (*ramus inferior ossis pubis*) is thin and flattened. It passes outward and downward, becoming narrower as it descends, and joins with the ramus of the ischium. Its **anterior surface** is rough, for the origin of muscles—the Gracilis along its inner border; a portion of the Obturator externus where it enters into the formation of the foramen of that name; and between these two muscles the Adductores brevis and magnus from within outward. The **posterior surface** is smooth, and gives origin to the Obturator internus, and, close to the inner margin, to the Compressor urethrae. The **inner border** is thick, rough, and everted, especially in females. It presents two ridges, separated by an intervening space. The ridges extend downward, and are continuous with similar ridges on the ascending ramus of the ischium; to the external one is attached the deep layer of the superficial perineal fascia, and to the internal one the superficial layer of the triangular ligament of the perineum. The **outer border** is thin and sharp, forms part of the circumference of the obturator foramen, and gives attachment to the obturator membrane.

The **Cotyloid Cavity, or Acetabulum**, is a deep, cup-shaped, hemispherical depression, directed downward, outward, and forward; formed *internally* by the os pubis, *above* by the ilium, *behind* and *below* by the ischium, a little less than two-fifths being formed by the ilium, a little more than two-fifths by the ischium, and the remaining fifth by the pubic bone. It is bounded by a prominent uneven rim, which is thick and strong above, and serves for the attachment of the cotyloid ligament, which contracts its orifice and deepens the surface for articulation. It presents below a deep notch, the **cotyloid notch** (*incisura acetabuli*), which is continuous with a circular depression, the **fossa of the acetabulum** (*fossa acetabuli*), at the bottom of the cavity; this depression is perforated by numerous apertures, lodges a mass of fat, and its margins, as well as those of the notch, serve for the attachment of the ligamentum teres. In front, above and behind the fossa acetabuli, is a concave rim of bone (*facies lunata*). The cotyloid notch is converted, in the natural state, into a foramen by a dense ligamentous band, the **transverse ligament**, which passes across it. Through this foramen the nutrient vessels and nerves of the joint pass.

The **Obturator, or Thyroid Foramen** (*foramen obturatum*), is a large aperture situated between the ischium and os pubis. In the male it is large, of an oval form, its longest diameter being obliquely from before backward; in the female it is smaller and more triangular. It is bounded by a thin, uneven margin, to which a strong membrane is attached, and presents, anteriorly, a deep groove, the **obturator groove** (*sulcus obturatorius*), which runs from the pelvis obliquely inward and downward. This groove is converted into a foramen by the obturator membrane, and transmits the obturator vessels and nerve.

Structure.—This bone consists of much cancellous tissue, especially where it is thick, enclosed between two layers of dense, compact tissue. In the thinner parts of the bone, as at the bottom of the acetabulum and centre of the iliac fossa, it is usually semitransparent, and composed entirely of compact tissue.

Development (Fig. 169).—From *eight centres*—three primary, *one* for the ilium, *one* for the ischium, and *one* for the os pubis; and *five secondary*, *one* for the crest of the ilium, *one* for the anterior inferior spinous process (said to occur more frequently in the male than in the female), *one* for the tuberosity of the ischium, *one* for the symphysis pubis (more frequent in the female than the male), and *one* or more for the Y-shaped piece at the bottom of the acetabulum. These

From eight centres { Three primary (Ilium, Ischium, and Os Pubis).
Five secondary.

The three primary centres unite through a Y-shaped piece about puberty. Epiphyses appear about puberty, and unite about the twenty-fifth year.

FIG. 169.—Plan of the development of the os innominatum.

various centres appear in the following order: First, in the ilium, at the lower part of the bone, immediately above the sciatic notch, at about the eighth or ninth week; secondly, in the body of the ischium, at about the third month of fetal life; thirdly, in the body of the os pubis, between the fourth and fifth months. At birth the three primary centres are quite separate, the crest, the bottom of the acetabulum, the ischial tuberosity, and the rami of the ischium and pubes being still cartilaginous. At about the seventh or eighth year the rami of the os pubis and ischium are almost completely united by bone. About the twelfth year the three divisions of the bone have extended their growth into the bottom of the acetabulum, being separated from each other by a Y-shaped portion of cartilage, which now presents traces of ossification, often by two or more centres. One of these, the *os acetabuli*, appears about the age of twelve, between the ilium and os pubis, and fuses with them about the age of eighteen. It forms the pubic part of the acetabulum. The ilium and ischium then become joined, and lastly the os pubis to the ischium, through the

intervention of this Y-shaped portion. At about the age of puberty ossification, takes place in each of the remaining portions, and they become joined to the rest of the bone between the twentieth and twenty-fifth years. Separate centres are frequently found for the pubic and ischial spines.

Articulations.—With its fellow of the opposite side, the sacrum, and femur.

Attachment of Muscles.—To the ilium, *sixteen*. To the outer lip of the crest, the Tensor vaginæ femoris, Obliquus externus abdominis, and Latissimus dorsi; to the internal lip, the Iliacus, Transversalis, Quadratus lumborum, and Erector spinæ; to the interspace between the lips, the Obliquus internus. To the outer surface of the ilium, the Gluteus maximus, Gluteus medius, Gluteus minimus, reflected tendon of the Rectus femoris; to the upper part of the great sacrosciatic notch, a portion of the Piriformis; to the internal surface, the Iliacus; to that portion of the internal surface below the iliopectineal line, the Obturator internus to the internal surface of the posterior superior spine, and the Multifidus spinæ; to the anterior border, the Sartorius and straight tendon of the Rectus femoris. To the ischium, *thirteen*. To the outer surface of the ramus, the Obturator externus and Adductor magnus; to the internal surface, the Obturator internus and Erector penis. To the spine, the Gemellus superior, Levator ani, and Coccygeus. To the tuberosity, the Biceps, Semitendinosus, Semimembranosus, Quadratus femoris, Adductor magnus, Gemellus inferior, Transversus perinei, Erector penis. To the pubis, *sixteen*: Obliquus externus, Obliquus internus, Transversalis, Rectus abdominis, Pyramidalis, Psoas parvus, Pectineus, Adductor magnus, Adductor longus, Adductor brevis, Gracilis, Obturator externus and internus, Levator ani, Compressor urethrae, and occasionally a few fibres of the Accelerator urinae.

THE PELVIS (Figs. 170, 171).

The **pelvis** is stronger and more massively constructed than either the cranial or thoracic cavity; it is a bony ring, interposed between the lower end of the vertebral column, which it supports, and the lower extremities, upon which it rests. It is composed of four bones—the two **ossa innominata**, which bound it on either side and in front, and the **sacrum** and **coccyx**, which complete it behind. The pelvis is divided by an oblique plane passing through the prominence of the sacrum, the iliopectineal line, and the upper margin of the symphysis pubis into the **false** and **true pelvis**.

The **False Pelvis** (*pelvis major*) is the expanded portion of the pelvic cavity which is situated above this plane. It is bounded on each side by the ossa ilii; in front it is incomplete, presenting a wide interval between the spinous processes of the ilia on either side, which is filled up in the recent state by the parietes of the abdomen; behind, in the middle line, is a deep notch. This broad, shallow cavity is fitted to support the intestines and to transmit part of their weight to the anterior wall of the abdomen, and is, in fact, really a portion of the abdominal cavity. The term false pelvis is incorrect, and this space ought more properly to be regarded as part of the hypogastric and iliac regions of the abdomen.

The **True Pelvis** (*pelvis minor*) is that part of the pelvic cavity which is situated below the iliopectineal line. It is smaller than the false pelvis, but its walls are more perfect. For convenience of description it is divided into a **superior circumference**, or **inlet**, an **inferior circumference**, or **outlet**, and a **cavity**.

The **superior circumference**, or **inlet** (*apertura pelvis superior*), forms the **brim of the pelvis**, the included space being called the **inlet**. It is formed by the iliopectineal line, completed in front by the crests of the pubic bones, and behind by the anterior margin of the base of the sacrum and sacrovertebral angle. The inlet of the pelvis is somewhat heart-shaped, obtusely pointed in front, diverging on either side, and encroached upon behind by the projection forward of the promontory of the sacrum. It has three principal diameters—antero-posterior (sacropubic), transverse, and oblique. The **antero-posterior** or **conjugate diameter** (*conjugata*) extends from the sacrovertebral angle to the symphysis pubis. Its average measurement is four inches in the male and four and three-fifths inches in the female. The **transverse diameter** (*diameter transversa*) extends across the greatest width of the inlet, from the middle of the brim on one side to the

same point on the opposite; its average measurement is five inches in the male, five and one-fourth inches in the female. The **oblique diameter** (*diameter obliqua*) extends from the margin of the pelvis, corresponding to the iliopectineal eminence

FIG. 170.—Male pelvis (adult).

on one side, to the sacroiliac articulation on the opposite side; its average measurement is four and one-fourth inches in the male and five in the female.

The **cavity** of the true pelvis is bounded in *front* by the symphysis pubis; *behind*, by the concavity of the sacrum and coccyx, which, curving forward above and

FIG. 171.—Female pelvis (adult).

below, contracts the inlet and outlet of the canal; and *laterally* it is bounded by a broad, smooth, quadrangular surface of bone, corresponding to the inner surface of the body of the ischium and that part of the ilium which is below the ilio-

pectineal line. The cavity is shallow in front, measuring at the symphysis an inch and a half in depth, three inches and a half in the middle, and four inches and a half posteriorly. From this description it will be seen that the cavity of the pelvis is a short, curved canal, considerably deeper on its posterior than on its anterior wall. This cavity contains, in the recent subject, the rectum, bladder, and some of the organs of generation. The rectum is placed at the back of the pelvis, and corresponds to the curve of the sacrococcygeal segment of the vertebral column; the bladder in front, behind the symphysis pubis. In the female the uterus and vagina occupy the interval between these viscera.

The **lower circumference** is very irregular; the space enclosed by it is called the **outlet** (*apertura pelvis inferior*). It is bounded by three prominent eminences—one posterior, formed by the point of the coccyx; and one on each side, the tuberosities of the ischia. These eminences are separated by three notches; one in front, the **pubic arch** (*arcus pubis*), formed by the convergence of the rami of the ischia and pubic bones on each side. The other notches, one on each side, are formed by the sacrum and coccyx behind, the ischium in front, and the ilium above; they are called the **sacrosciatic notches**; in the natural state they are converted into foramina by the lesser and greater sacrosciatic ligaments. In the recent state, when the ligaments are *in situ*, the outlet of the pelvis is lozenge-shaped, bounded in front by the subpubic ligament and the rami of the os pubis and ischium; on each side by the tuberosities of the ischia; and behind by the great sacrosciatic ligaments and the tip of the coccyx.

The diameters of the outlet of the pelvis are two, antero-posterior and transverse. The **antero-posterior diameter** extends from the tip of the coccyx to the lower part of the symphysis pubis; its average measurement is three and three-quarter inches in the male and four and one-half inches in the female. The antero-posterior diameter varies with the length of the coccyx, and is capable of increase or diminution on account of the mobility of that bone. During labor the coccyx may be bent back so that the conjugate is increased one inch, or even one and one-fourth inches. The **transverse diameter** extends from the posterior part of one ischiatic tuberosity to the same point on the opposite side; the average measurement is three and one-half inches in the male and four and three-fourths in the female.¹

Position of the Pelvis.—In the erect posture the pelvis is placed obliquely with regard to the trunk of the body; the bony ring, which forms the brim of the true pelvis, is placed so as to form an angle of about 60 to 65 degrees with the ground on which we stand (*inclinatio pelvis*). The pelvic surface of the symphysis pubis looks upward and backward, the concavity of the sacrum and coccyx downward and forward, the base of the sacrum in well-formed female bodies being nearly four inches above the upper border of the symphysis pubis, and the apex of the coccyx a little more than half an inch above its lower border. In consequence of the obliquity of the pelvis the line of gravity of the head, which passes through the middle of the odontoid process of the axis and through the points of junction of the curves of the vertebral column to the sacrovertebral angle, descends toward the front of the cavity, so that it bisects a line drawn transversely through the middle of the heads of the thigh bones. And thus the centre of gravity of the head is placed immediately over the heads of the thigh bones on which the trunk is supported.

¹ The measurements of the pelvis given above are, I believe, fairly accurate, but different measurements are given by various authors, no doubt due in a great measure to differences in the physique and stature of the population from whom the measurements have been taken. The accompanying chart has been formulated to show the measurements of the pelvis which are adopted by many obstetricians.—[EDITOR.]

DIAMETERS OF THE TRUE PELVIS IN WOMAN.

	<i>Antero-posterior.</i>	<i>Oblique.</i>	<i>Transverse.</i>
Of inlet . . .	4 $\frac{3}{8}$ inches (118 mm.)	5 inches (127 mm.)	5 $\frac{1}{4}$ inches (135 mm.)
Of outlet . . .	4 $\frac{1}{2}$ inches (115 mm.)		4 $\frac{3}{4}$ inches (120 mm.)

Axes of the Pelvis (Fig. 172).—The **plane of the inlet** of the true pelvis will be represented by a line drawn from the base of the sacrum to the upper margin of the symphysis pubis. A line carried at right angles with this at its middle would correspond at one extremity with the umbilicus, and at the other with the middle of the coccyx; the **axis of the inlet** is therefore directed downward and backward. The **axis of the outlet**, prolonged upward, would touch the base of

FIG. 172.—Vertical section of the pelvis, with lines indicating the axis of the pelvis.

the sacrum, and is therefore directed downward and forward. The **axis of the cavity** is curved like the cavity itself; this curve corresponds to the concavity of the sacrum and coccyx, the extremities being indicated by the central points of the inlet and outlet. A knowledge of the direction of these axes serves to explain the course of the fetus in the passage through the pelvis during parturition.

Differences between the Male and Female Pelvis.

—The female pelvis, looked at as a whole, is distinguished from the male by the bones being more delicate, by its width being greater and its depth smaller. The whole pelvis is less massive, and its bones are lighter and more slender, and its muscular impressions are slightly marked. The iliac fossæ are shallow, and the anterior iliac spines widely separated; hence the greater prominence of the hips. The **inlet** in the female is larger than in the male; it is more nearly circular, and the sacrovertebral angle projects less forward. The **cavity** is shallower and wider; the sacrum is shorter, wider, and less curved; the obturator foramina are triangular, and smaller in size than in the male. The **outlet** is larger and the coccyx more movable. The

FIG. 173.—Diameters of the pelvic inlet in the female.

spines of the ischia project less inward. The tuberosities of the ischia and the acetabula are wider apart. The **pubic arch** is wider and more rounded than in the male, where it is an angle rather than an arch. In consequence of this the

width of the fore part of the pelvic outlet is much increased and the passage of the fetal head facilitated.

The size of the pelvis varies not only in the two sexes, but also in different members of the same sex. This does not appear to be influenced in any way by the height of the individual. Women of short stature, as a rule, have broad pelvises. Occasionally the pelvis is equally contracted in all its dimensions, so much so that all its diameters measure an inch less than the average, and this even in women of average height and otherwise well formed. The principal divergences, however, are found at the inlet, and affect the relation of the antero-posterior to the transverse diameter. Thus we may have a pelvis the inlet of which is elliptical either in a transverse or antero-posterior direction; the transverse diameter in the former and the antero-posterior in the latter greatly exceeding the other diameters. Again, the inlet of the pelvis in some instances is seen to be almost circular. The same differences are found in various races. European women are said to have the most roomy pelvises. That of the negress is smaller, circular in shape, and with a narrow pubic arch. The Hottentots and Bushwomen possess the smallest pelvises.

FIG. 174.—Diameters of the pelvic outlet in the female.

In the *fetus* and for several years after birth the pelvis is small in proportion to that of the adult. The cavity is deep and the projection of the sacrovertebral angle less marked. The generally accepted opinion that the female pelvis does not acquire its sexual characters until after puberty has been shown by recent observations¹ to be erroneous, the characteristic differences between the male and female pelvis being distinctly indicated as early as the fourth month of fetal life. At birth these differences are distinct (Romiti), the female pelvis possessing less straight ilia, a broader subpubic arch, and less height than the male.

Surface Form.—The pelvic bones are so thickly covered with muscles that it is only at certain points that they approach the surface and can be felt through the skin. In front, the anterior superior spinous process is easily recognized; a portion of it is subcutaneous, and in thin subjects may be seen to stand out as a prominence at the outer extremity of the fold of the groin. In fat subjects its position is marked by an oblique depression among the surrounding fat, at the bottom of which the bony process may be felt. Proceeding upward and outward from this process, the crest of the ilium may be traced throughout its whole length, sinuously curved. It is represented, in muscular subjects, on the surface, by a groove or furrow, the *iliac furrow*, caused by the projection of fleshy fibres of the External oblique muscles of the abdomen; the

¹ Fehling, *Zeitschr. für Geburt. u. Gynäk.*, Band ix and x; and Arthur Thomson, *Journal of Anatomy and Physiology*, vol. xxxiii.

iliac furrow lies slightly below the level of the crest. It terminates behind in the posterior superior spinous process, the position of which is indicated by a slight depression on a level with the spinous process of the second sacral vertebra. Between the two posterior superior spinous processes, but at a lower level, is to be felt the spinous process of the third sacral vertebra (see page 68). Another part of the bony pelvis easily accessible to touch is the tuberosity of the ischium, situated beneath the gluteal fold, and, when the hip is flexed, it is easily felt, as it is then to a great extent uncovered by muscle. Finally, the spine of the os pubis can always be readily felt, and constitutes an important surgical guide, especially in connection with the subject of hernia. It is nearly in the same horizontal line with the upper edge of the great trochanter. In thin subjects it is very apparent, but in the obese it is obscured by the pubic fat. It can, however, be detected by everting the thigh and following up the tendon of origin of the Adductor longus muscle.

Applied Anatomy.—There is arrest of development in the bones of the pelvis in cases of *extroversion of the bladder*; the anterior part of the pelvic girdle being deficient, the bodies of the pubic bones imperfectly developed, and the symphysis absent. The pubic bones are separated to the extent of from two to four inches, the superior rami shortened and directed forward, and the obturator foramen diminished in size, narrowed, and turned outward. The iliac bones are straightened out more than normal. The sacrum is very peculiar. The lateral curve, instead of being concave, is flattened out or even convex, with the iliosacral facets turned more outward than normal, while the vertical curve is straightened.¹

Fractures of the pelvis are divided into fractures of the false pelvis and of the true pelvis. Fractures of the false pelvis vary in extent: a small portion of the iliac crest may be broken or one of the spinous processes may be torn off, and this may be the result of muscular action; or the bone may be extensively comminuted. This latter accident is the result of some crushing violence, and may be complicated with fracture of the true pelvis. These cases may be accompanied by injury to the intestine as it lies in the hollow of the bone, or to the iliac vessels as they course along the margin of the true pelvis. Fractures of the true pelvis generally occur through the ascending ramus of the os pubis and the ramus of the ischium, as this is the weakest part of the bony ring, and may be caused either by crushing violence applied in an antero-posterior direction, when the fracture occurs from direct force, or by compression laterally, when the acetabula are pressed together, and the bone gives way in the same place from indirect violence. Occasionally the injury may be double, a break occurring on both sides of the body. In fracture of the true pelvis the contained viscera are liable to be damaged; the small intestines, the urethra, the bladder, the rectum, the vagina, and even the uterus, in the female, have all been lacerated by a displaced fragment. Fractures of the acetabulum are occasionally met with; either a portion of the rim may be broken off, or a fracture may take place through the bottom of the cavity, and the head of the femur may be driven inward and project into the pelvic cavity. Separation of the Y-shaped cartilage at the bottom of the acetabulum may also occur in the young subject, dispersing the bone into its three anatomical portions.

The *sacrum* is seldom broken. The cause is direct violence—i. e., blows, kicks, or falls on the part. The lesion may be complicated with injury to the nerves of the sacral plexus, leading to paralysis and loss of sensation in the lower extremity or to incontinence of feces from paralysis of the Sphincter ani.

Fracture of the coccyx is a very rare injury, but does occasionally take place. Some supposed dislocations of this bone have been fractures and so have some of the cases diagnosticated as coccygodynia. A fracture of the coccyx is due to direct force.

The pelvic bones often undergo important deformity in *rhachitis*, the effect of which in the adult woman may interfere seriously with childbearing. The deformity is due mainly to the weight of the spine and trunk, which presses on the sacrovertebral angle and greatly increases it, so that the antero-posterior diameter of the pelvis is diminished. But, in addition to this, the weight of the viscera on the venter ilii causes the ilia to expand and the tuberosities of the ischia to incurve. In *osteomalacia* also great deformity may occur. The weight of the trunk causes an increase in the sacrovertebral angle and a lessening of the antero-posterior diameter of the inlet, and at the same time the pressure of the acetabula on the heads of the thigh bones causes these cavities, with the adjacent bone, to be pushed upward and backward, so that the oblique diameters of the pelvis are also diminished, and the cavity of the pelvis assumes a tri-radiate shape, with the symphysis pubis pushed forward.

THE THIGH.

The **thigh** is that portion of the lower extremity which is situated between the pelvis and the knee. It consists in the skeleton of a single bone, the **femur**.

¹ Wood, Heath's Dictionary of Practical Surgery, i, 426.

The Femur, or Thigh Bone (Figs. 175, 177).

The **femur** (*femur*) is the longest,¹ largest, and strongest bone in the skeleton, and almost perfectly cylindrical throughout the greater part of its extent. In the erect posture it is not vertical, being separated from its fellow above by a considerable interval, which corresponds to the entire breadth of the pelvis, but inclining gradually downward and inward, so as to approach its fellow toward its lower part, for the purpose of bringing the knee-joint near the line of gravity of the body. The degree of this inclination varies in different persons, and is greater in the female than the male, on account of the greater breadth of the pelvis. The femur, like other long bones; is divisible into a shaft and two extremities.

The **Upper or Proximal Extremity** presents for examination a head, a neck, and a greater and a lesser trochanter.

The **head** (*caput femoris*), which is globular and forms rather more than a hemisphere, is directed upward, inward, and a little forward, the greater part of its convexity being above and in front. Its surface is smooth, coated with hyaline cartilage in the recent state, except at a little behind and below its centre, where there is an **ovoid depression** (*fovea capitis femoris*), for the attachment for the ligamentum teres.

The **neck** (*collum femoris*) is a flattened pyramidal process of bone which connects the head with the shaft. It varies in length and obliquity at various periods in life and under different circumstances. The angle is widest in infancy, and becomes lessened during growth, so that at puberty it forms a gentle curve from the

FIG. 175.—Right femur. Anterior surface.

¹ In a man six feet high it measures eighteen inches—one-fourth of the whole body stature.

axis of the shaft. In the adult it forms an angle of about 125 degrees with the shaft, but varies in inverse proportion to the development of the pelvis and the stature. In consequence of the prominence of the hips and widening of the pelvis in the female, the neck of the thigh bone forms more nearly a right angle with the shaft than it does in the male. The neck is flattened from before backward, contracted in the middle, and broader at its outer extremity, where it is connected with the shaft, than at its summit, where it is continuous with the head. The vertical diameter of the outer half is increased by the thickening of the lower edge, which slopes downward to join the shaft at the lesser trochanter; as a result of this the outer half of the neck is flattened from before backward, and its vertical diameter measures one-third more than the antero-posterior. The inner half is smaller and of a more circular shape. The *anterior surface* of the neck is perforated by numerous vascular foramina. The *posterior surface* is smooth, and is broader and more concave than the anterior; it gives attachment to the posterior part of the capsular ligament of the hip-joint, about half an inch above the posterior intertrochanteric line. The *superior border* is short and thick, and terminates externally at the great trochanter; its surface is perforated by large foramina. The *inferior border*, long and narrow, curves a little backward, to terminate at the lesser trochanter.

FIG. 176.—Upper extremity of the femur viewed from behind and above.

The **trochanters** are prominent processes of bone which afford leverage to the muscles which rotate the thigh on its axis. They are two in number, the greater and the lesser.

The **greater trochanter** (*trochanter major*) is a large, irregular, quadrilateral eminence, situated at the outer side of the neck, at its junction with the upper part of the shaft. It is directed a little outward and backward, and in the adult is about three-quarters of an inch lower than the head. It presents for examination two surfaces and four borders. The *external surface*, quadrilateral in form, is broad, rough, convex, and marked by a prominent diagonal impression, which extends from the posterior superior to the anterior inferior angle, and serves for the attachment of the tendon of the Gluteus medius. Above the impression is a triangular surface, sometimes rough for part of the tendon of the same muscle, sometimes smooth for the interposition of a bursa between that tendon and the bone. Below and behind the diagonal line is a smooth, triangular surface, over which the tendon of the Gluteus maximus muscle plays, a bursa being interposed. The *internal surface* is of much less extent than the external, and presents

at its base a deep depression, the **digital or trochanteric fossa** (*fossa trochanterica*), for the attachment of the tendon of the Obturator externus muscle; above and in front of this an impression for the attachment of the Obturator internus and Gemelli. The **superior border** is free; it is thick and irregular, and marked near the centre by an impression, which extends onto the internal surface, for the attachment of the Pyliformis. The **inferior border corresponds** to the point of junction of the base of the trochanter with the outer surface of the shaft; it is marked by a rough, prominent, slightly curved ridge, which gives origin to the upper part of the Vastus externus muscle. The **anterior border** is prominent, somewhat irregular, as well as the surface of bone immediately below it; it affords attachment at its outer part to the Gluteus minimus. The **posterior border** is very prominent, and appears as a free, rounded edge, which forms the back part of the digital fossa.

The **lesser trochanter** (*trochanter minor*) is a conical eminence which varies in size in different subjects; it projects from the lower and back parts of the base of the neck. Its base is triangular, and connected with the adjacent parts of the bone by three well-marked borders; two of these are above — the **internal border**, continuous with the lower border of the neck, the **external border**, with the posterior intertrochanteric line — while the **inferior border** is continuous with the middle division of the *linea aspera*. Its summit, which is directed inward and backward, is rough and gives insertion to the tendon of the Iliopsoas. The Iliacus is also inserted into the shaft below the lesser trochanter between the Vastus internus in front and the Pectineus behind.

FIG. 177.—Right femur. Posterior surface.

A well-marked prominence of variable size, which projects from the upper and front part of the neck at its junction with the great trochanter, is called the **tubercle of the femur**; it is the point of meeting of five muscles—the Gluteus minimus externally, the Vastus externus below, and the tendon of the Obturator internus and Gemelli internally. Running obliquely downward and inward from the tubercle is the **spiral line of the femur**, or **anterior intertrochanteric line** (*linea intertrochanterica*); it winds around the inner side of the shaft, below the lesser trochanter, and terminates about two inches below this eminence in the *linea aspera*. Its upper half is rough, and affords attachment to the iliofemoral ligament of the hip-joint; its lower half is less prominent, and gives origin to the upper part of the Vastus internus. Running obliquely downward and inward from the summit of the great trochanter on the posterior surface of the neck is a very prominent,

FIG. 178.—Diagram of linea aspera.
(After Birmingham.)

well-marked ridge, the **posterior intertrochanteric line** (*crista intertrochanterica*). Its upper half forms the posterior border of the great trochanter, and its lower half runs downward and inward to the upper and back part of the lesser trochanter. A slight ridge sometimes commences about the middle of the posterior intertrochanteric line, and passes vertically downward for about two inches along the back part of the shaft; it is called the **linea quadrati**, and gives attachment to the Quadratus femoris and a few fibres of the Adductor magnus muscles.¹

The Shaft (*corpus femoris*).—The shaft, almost cylindrical in form, is a little broader above than in the centre, and somewhat flattened below, from before backward. It is slightly arched, so as to be convex in front and concave behind, where it is strengthened by a prominent longitudinal ridge, the **linea aspera**. It presents for examination three borders, separating three surfaces. Of the three borders, one, the *linea aspera*, is posterior; the other two are placed laterally.

The **linea aspera** (Fig. 178) is a prominent longitudinal ridge or crest, on the middle third of the bone, presenting an **external lip** (*labium laterale*), an **internal lip** (*labium mediale*), and a rough **intermediate space**. Above, this crest is prolonged by three ridges. The most **external ridge** is very rough, and is continued almost

vertically upward to the base of the great trochanter. It is sometimes termed the **gluteal ridge** (*tuberositas glutea*), and gives attachment to part of the Gluteus maximus muscle; its upper part is sometimes elongated into a roughened crest, on which is a more or less well-marked, rounded tubercle, a **rudimental third trochanter** (*trochanter tertius*). The **middle ridge** (*linea pectinea*), the least distinct, is continued to the base of the lesser trochanter, and the **internal ridge** is lost above in the spiral line of the femur. Below, the *linea aspera* is prolonged by two ridges, which pass to the condyles and enclose between them a triangular space, the **popliteal surface** (*planum popliteum*), upon which rests the popliteal artery. Of these two ridges, the *outer* one is the more prominent, and descends to the summit of the outer condyle. The *inner* one is less marked, especially at

¹ Generally there is merely a slight thickening about the centre of the intertrochanteric line, marking the point of attachment of the Quadratus femoris. This is termed by some anatomists the *tubercle of the Quadratus*.

its upper part, where it is crossed by the femoral artery. It terminates, below, at the summit of the internal condyle, in a small tubercle, the **adductor tubercle**, which affords attachment to the tendon of the Adductor magnus. To the inner lip of the linea aspera and its inner prolongation above and below arises the Vastus internus, and to the outer lip and its outer prolongation above arises the Vastus externus. The Adductor magnus is attached to the linea aspera, to its outer prolongation above and its inner prolongation below. Between the Vastus externus and the Adductor magnus are attached two muscles—viz., the Gluteus maximus above, and the short head of the Biceps femoris below. Between the Adductor magnus and the Vastus internus four muscles are attached—the Iliacus and Pectineus above, the Adductor brevis and Adductor longus below. A little below the centre of the linea aspera is the **nutrient foramen**, the orifice of the **nutrient canal**, which is directed obliquely upward (proximally).

The **two lateral borders** of the femur are only slightly marked, the outer one extending from the anterior inferior angle of the great trochanter to the anterior extremity of the external condyle; the inner one from the spiral line at a point opposite the lesser trochanter, to the anterior extremity of the internal condyle. The internal border marks the limit of origin of the Crureus muscle internally.

The **anterior surface** includes that portion of the shaft which is situated between the two lateral borders. It is smooth, convex, broader above and below than in the centre, slightly twisted, so that its upper part is directed forward and a little outward, its lower part forward and a little inward. From the upper three-fourths of this surface the Crureus takes origin; the lower fourth is separated from the muscle by the intervention of the synovial membrane of the knee-joint and a bursa, and affords origin to the Subcrureus to a small extent.

The **external surface** includes the portion of bone between the external border and the outer lip of the linea aspera; it is continuous above with the outer surface of the great trochanter, below with the outer surface of the external condyle; from its upper three fourths arises the outer portion of the Crureus muscle.

The **internal surface** includes the portion of bone between the internal border and the inner lip of the linea aspera; it is continuous above with the lower border of the neck, below with the inner side of the internal condyle; it is covered by the Vastus internus muscle.

Lower or Distal Extremity.—The lower extremity, larger than the upper, is of a cuboidal form, flattened from before backward, and divided into two large eminences, the **condyles**, by an interval which presents a smooth depression in front called the **trochlea** (*facies patellaris*), and a notch of considerable size behind—the **intercondyloid notch** (*fossa intercondyloidea*). The **external condyle** (*condylus lateralis*) is the more prominent anteriorly, and is the broader both in the antero-posterior and transverse diameters. The **internal condyle** (*condylus medialis*) is the longer, and more prominent inferiorly. This difference in the length of the two condyles is only observed when the bone is perpendicular and depends upon the obliquity of the thigh bones, in consequence of their separation above at the articulation with the pelvis. If the femur is held obliquely, the surfaces of the two condyles will be seen to be nearly horizontal. The two condyles are directly continuous in front, and form a smooth, trochlear surface, the **trochlea**. The trochlea and the inferior surface of the condyles constitute the articular surface of the lower end of the femur, and are covered by hyaline cartilage in the recent state. The trochlea articulates with the patella. It presents a median groove, which extends downward and backward to the intercondyloid notch; and two lateral convexities, of which the external is the broader, more prominent, and prolonged farther upward upon the front of the outer condyle. The external border of this articular surface is also more prominent, and ascends higher than the internal one. The inferior surfaces of the condyles are convex from side to side

and from before backward, and articulate with the corresponding surfaces of the tibia. They are marked off from the trochlea by two irregular grooves. The outer groove runs obliquely outward and forward from the anterior extremity of the intercondyloid notch to the outer side of the external condyle. The inner is less well marked and placed farther forward than the one on the external condyle; it extends obliquely outward and backward. In the grooves the semilunar cartilages fit when the knee is extended. The opposed surfaces of the condyles form the lateral walls of the intercondyloid notch.

FIG. 179.—Lower extremity of right femur viewed from below.

The **outer surface** of the external condyle presents, a little behind its centre, an eminence, the **outer tuberosity**, or **outer epicondyle** (*epicondylus lateralis*); it is less prominent than the inner tuberosity, and gives attachment to the external lateral ligaments of the knee. Immediately beneath it is the **popliteal groove** (*sulcus popliteus*), which commences at a depression a little behind the centre of the lower border of this surface; the front part of this depression gives origin to the Popliteus muscle, the tendon of which is lodged in the groove during flexion of the knee. The groove is smooth, covered with hyaline cartilage in the recent state, and runs upward and backward to the posterior extremity of the condyle. The posterior extremity is convex and smooth; just above and to the outer side of the articular surface is a depression for the tendon of the outer head of the Gastrocnemius, above which is the origin of the Plantaris.

FIG. 180.—Scheme showing disposition of principal cancellous lamellae in upper extremity of femur.

The **inner surface** of the inner condyle presents a convex eminence, the **inner tuberosity**, or **inner epicondyle** (*epicondylus medialis*), rough for the attachment of the internal lateral ligament. Just above the auricular surface of this condyle, behind, is a depression for the tendon of origin of the inner head of the Gastrocnemius.

The intercondyloid notch is bounded laterally by the opposed surfaces of the condyles, and lodges the crucial ligaments of the knee-joints. The inner wall of the notch at its front part has attached to it the posterior crucial ligament. The external wall at its upper and back part affords attachment to the anterior crucial ligament. Above it is separated from the popliteal surface by a ridge—the *linea intercondyloidea*.

Structure.—The shaft of the femur is a cylinder of compact tissue, hollowed by a large medullary canal. The cylinder is of great thickness and density in the middle third of the shaft, where the bone is narrowest and the medullary canal well formed; but above and below this the cavity gradually becomes smaller, owing to a separation of the layers of the bone into cancelli, which project into the medullary canal and finally obliterate it, so that the upper and lower ends of the shaft, and the articular extremities more especially, consist of cancellated tissue invested by a thin, compact layer.

The arrangement of the cancelli in the ends of the femur is remarkable. In the upper end they are arranged in two sets. One, starting from the top of the head, the upper surface of the neck, and the great trochanter, converge to the inner circumference of the shaft (Figs. 180 and 181); these are placed in the direction of greatest pressure, and serve to support the vertical weight of the body. The second set are planes of lamellæ intersecting the former nearly at right angles, and are situated in the line of the greatest tension—that is to say, along the lines in which the muscles and ligaments exert their traction. In the head of the bone these planes are arranged in a curved form, in order to strengthen the bone when exposed to pressure in all directions. In

FIG. 181.—Longitudinal section of head and neck of femur.

the midst of the cancellous tissue of the neck is a vertical plane of compact bone, the **femoral spur** (*calcar femorale*), which commences at the point where the neck joins the shaft just external to the lesser trochanter, and extends in the direction of the digital fossa (Fig. 182). This material strengthens this portion of the bone. Another point in connection with the structure of the neck of the femur requires mention, especially on account of its influence on the production of fracture in this situation. It will be noticed that a considerable portion of the great trochanter lies behind the level of the posterior surface of the neck; and if a section be made through the trochanter at this level, it will be seen that the posterior wall of the neck is prolonged into the trochanter. This prolongation is termed by Bigelow the **true neck**,¹ and forms a thin, dense plate of bone, which passes beneath the posterior intertrochanteric ridge toward the outer surface of the bone. In the lower end the cancelli spring on all sides from the inner surface of the cylinder, and descend in a perpendicular direction to the articular surface, the cancelli being strongest and having a more accurately perpendicular course above the condyles. In addition

¹ Bigelow on the Hip, p. 121.

to this, however, horizontal planes of cancellous tissue are to be seen, so that the spongy tissue in this situation presents an appearance of being mapped out into a series of rectangular areas.

Articulations.—With *three* bones—the os innominatum, tibia, and patella.

Development (Fig. 183).—The femur is developed from *five* centres—one for the shaft, one for each extremity, and one for each trochanter. Of all the long bones, except the clavicle, it is the first to show traces of ossification; this commences in the shaft, at about the seventh week of fetal life, the centres of ossification in the epiphyses appearing in the following order: First, in the lower end of the bone, at the ninth month of fetal life¹ (from this the condyles and tuberosities are formed); in the head at the end of the first year after birth; in the great trochanter, during the fourth year; and in the lesser trochanter, between the thirteenth and fourteenth years. The order in which the epiphyses are joined to the shaft is the reverse of that of their appearance; their junction does not commence until after puberty, the lesser trochanter being first joined, then the great, then the head, and lastly the inferior extremity (the first in which ossification commenced), which is not united until the twentieth year. Because of this late union, the lower extremity of the femur has been called the "growing end" of the bone, and early arrest of ossification here results in more or less marked diminution of stature.

FIG. 182.—Calcar femorale.

FIG. 183.—Plan of the development of the femur. From five centres.

Attachment of Muscles.—To *twenty-three*. To the great trochanter: the Gluteus medius, Gluteus minimus, Piriformis, Obturator internus, Obturator externus, Gemellus superior, and Gemellus inferior. To the lesser trochanter: the Psoas magnus and the Iliacus below it. To the shaft: the Quadratus femoris, Vastus externus, Gluteus maximus, short head of the Biceps femoris, Vastus internus, Adductor magnus, Pectineus, Adductor brevis, Adductor longus, Crureus, and Subcrureus. To the condyles: the Gastrocnemius, Plantaris, and Popliteus.

Surface Form.—The femur is covered with muscles, so that in fairly muscular subjects the shaft is not to be detected through its fleshy covering, and the only parts accessible to the touch are the outer surface of the great trochanter and the lower expanded end of the bone. The external surface of the great trochanter may be felt, especially in certain positions of the limb. Its position is generally indicated by a depression, owing to the thickness of the Gluteus medius and

¹ This is said to be the only epiphysis in which ossification begins before birth; though, according to some observers, the centre for the upper epiphysis of the tibia also appears before birth.

minimus, which project above it. When, however, the thigh is flexed, and especially if crossed over the opposite one, the trochanter produces a blunt eminence on the surface. The upper border is about on a line with the spine of the os pubis, and its exact level is indicated by a line drawn from the anterior superior spinous process of the ilium, over the outer side of the hip, to the most prominent point of the tuberosity of the ischium. This is known as **Nelaton's line**. The outer and inner condyles of the lower extremity may easily be felt. The outer one is more subcutaneous than the inner one, and readily felt. The tuberosity on it is comparatively little developed, but can be more or less easily recognized. The inner condyle is more thickly covered, and this gives a general convex outline to this part, especially when the knee is flexed. The tuberosity on it is easily felt, and at the upper part of the condyle the sharp tubercle for the insertion of the tendon of the Adductor magnus can be recognized without difficulty. Occasionally, exostoses develop in the tendon of insertion of the Adductor magnus; these are the " *rider's bones* " of cavalry soldiers and horsemen. When the knee is flexed, and the patella situated in the interval between the condyles and the upper end of the tibia, a part of the trochlear surface of the femur can be made out above the patella.

Applied Anatomy.—There are one or two points about the ossification of the femur bearing on practice to which allusion must be made. It has been stated above that the lower end of the femur is the only epiphysis in which ossification has commenced at the time of birth. The presence of the ossific centre in newly born children found dead is, therefore, a proof that the child has arrived at the full period of uterogestation, and is always relied upon in medico-legal investigations. The position of the *epiphyseal line* should be carefully noted. It is on a level with the adductor tubercle, and the epiphysis does not, therefore, form the whole of the cartilage-clad portion of the lower end of the bone. It is essential to bear this point in mind in performing *excision of the knee*, since growth in length of the femur takes place chiefly from the lower epiphysis, and any interference with the epiphyseal cartilage in a young child would involve such ultimate shortening of the limb, from want of growth, as to render it almost useless. Separation of the *lower epiphysis* may take place up to the age of twenty, at which time it becomes completely joined to the shaft of the bone; but, as a matter of fact, few cases occur after the age of sixteen or seventeen. The epiphysis of the head of the femur is of interest principally on account of its being the seat of origin of a large number of cases of *tuberculous disease of the hip-joint*. The disease commences in the majority of cases in the highly vascular and growing tissue in the neighborhood of the epiphysis, and from here extends into the joint. In the condition known as *coxa vara* the head of the femur falls to a lower level than normal. The angle between the neck and shaft is greatly diminished and may become a right angle or the head may actually descend to a lower level than that of the trochanter. The neck is also bent with a convexity forward; *coxa vara* is due to *rhachitis*.

Fractures of the femur are divided, like those of the other long bones, into fractures of the upper end, of the shaft, and of the lower end. The fractures of the upper end may be classified into (1) fracture of the neck; (2) fracture at the junction of the neck with the great trochanter; (3) fracture of the great trochanter; and (4) separation of the epiphysis, either of the head or the great trochanter. The first of these, *fracture of the neck*, is usually termed *intracapsular fracture*, but this is scarcely a correct designation, as, owing to the attachment of the capsular ligament, the fracture may be partly within and partly without the capsule, when the fracture occurs at the lower part of the neck. It generally occurs in old people, principally women, and usually from a very slight degree of indirect violence. Probably the main cause of the fracture taking place in old people is in consequence of the degenerative changes which the bone has undergone. Merkel believes that it is mainly due to the absorption of the *calcar femorale*. These fractures are occasionally impacted. As a rule, they unite by fibrous tissue, and frequently no union takes place, and the surfaces of the fracture become smooth and eburnated. The lack of reparative power in intracapsular fracture is due to lack of apposition of the fragments and diminution in the amount of blood sent to the smaller fragment. The head of the bone receives blood from the neck through the reflected portions of the capsule and through the ligamentum teres. A fracture cuts off the supply by the neck and by the reflected portions of the capsule.

Fractures at the junction of the neck with the great trochanter are usually termed *extracapsular*, but this designation is also incorrect, as the fracture is partly within the capsule, owing to its attachment in front to the anterior intertrochanteric line, which is situated below the line of fracture. These fractures are produced by direct violence to the great trochanter, as from a blow or fall laterally on the hip. From the manner in which the accident is caused, the neck of the bone is driven into the trochanter, where it may remain impacted or the trochanter may split up into two or more fragments, and thus no fixation takes place.

Fractures of the great trochanter may be either "oblique fracture through the trochanter major, without implicating the neck of the bone" (Astley Cooper), or separation of the great trochanter. Most of the recorded cases of this latter injury occurred in young persons, and were probably cases of separation of the epiphysis of the great trochanter. Separation of the epiphysis of the head of the femur has been said to occur, but has probably never been verified by postmortem examination.

Fracture of the shaft may occur at any part, but the most usual situation is at or near the centre of the bone. They may be caused by direct or indirect violence or by muscular action. Fractures of the upper third of the shaft are almost always the result of indirect violence, while those of the lower third are the result, for the most part, of direct violence. In the middle third fractures occur from both forms of injury in about equal proportions. Fractures of the shaft are generally oblique, but they may be transverse, longitudinal, or spiral. The transverse fracture occurs most frequently in children. The fractures of the lower end of the femur include transverse fracture above the condyles, the most common; and this may be complicated by a vertical fracture between the condyles, constituting the *T-shaped fracture*. In these cases the popliteal artery is in danger of being wounded. Oblique fracture, separating either the internal or external condyle, and a longitudinal incomplete fracture between the condyles, may also take place.

The femur and also the bones of the leg are frequently the seat of *acute osteomyelitis* in young children. This is no doubt due to their greater exposure to injury, which is often the exciting cause of this disease. *Tumors* not infrequently are found growing from the femur, the most common forms being sarcoma, which may grow either from the periosteum or from the medullary tissue within the interior of the bone; and *exostosis*, which is commonly found originating in the neighborhood of the epiphyseal cartilage of the lower end.

Genu varum is a form of *bow-leg* in which the tibia and femur are curved outward, the knees being widely separated. Both extremities are usually affected. In early life the disease is due to rhachitis. In elderly people it may be due to arthritis deformans. *Genu valgum* (*knock-knee*) is a condition in which the knees are close together, the feet are wide apart, and the internal lateral ligament of the knee-joint is stretched. It is due to excessive growth of the inner condyle of the femur, the shaft of the femur curving inward. It may be due to rhachitis, attitude of an occupation, or flat-foot, and one or both knees may be affected.

THE LEG.

The skeleton of the leg consists of three bones—the **patella**, a large sesamoid bone, placed in front of the knee; the **tibia**; and the **fibula**.

The Patella, or Kneecap (Fig. 184).

The **patella** is a flat, triangular bone, situated at the anterior part of the knee-joint. It is usually regarded as a sesamoid bone, developed in the tendon of the Quadriceps extensor. It resembles such bones (1) in its being developed

in a tendon; (2) in its centre of ossification presenting a knotty or tuberculated outline; (3) in its structure being composed mainly of dense cancellous tissue, as in the other sesamoid bones. It serves to protect the front of the joint, and increases the leverage of the Quadriceps extensor by making it act at a greater angle. It presents an anterior and a posterior surface, three borders, and an apex.

FIG. 184.—Right patella. A. Anterior surface. B. Posterior surface.

Surfaces.—The **anterior surface** is convex, perforated by small apertures, for the passage of nutrient vessels, and marked by numerous rough, longitudinal striæ. This surface is covered, in the recent state, by an expansion from the tendon of the Quadriceps extensor, which is continuous below with the superficial fibres of the ligamentum patellæ. It is separated from the integument by a bursa.

The **posterior surface** presents a smooth, oval-shaped, articular surface (*facies articularis*), covered with hyaline cartilage in the recent state, and divided into two

facets by a vertical ridge, which descends from the superior border toward the inferior angle of the bone. The ridge corresponds to the groove on the trochlear surface of the femur, and the two facets to the articular surfaces of the two condyles; the outer facet, for articulation with the outer condyle, being broader and deeper. This character serves to indicate the side to which the bone belongs. Below the articular surface is a rough, convex, nonarticular depression, the lower half of which gives attachment to the ligamentum patellae, the upper half being separated from the head of the tibia by adipose tissue.

Borders.—The **superior border** (*basis patellae*) is thick, and sloped from behind, downward and forward; it gives attachment to that portion of the Quadriceps extensor which is derived from the Rectus femoris and Crureus muscles.

The **lateral borders** are thinner, converging below. They give attachment to that portion of the Quadriceps extensor derived from the external and internal Vasti muscles.

The **apex** (*apex patellae*) is pointed, and gives attachment to the ligamentum patellae.

Structure.—It consists of a nearly uniform, dense cancellous tissue covered by a thin compact lamina. The cancelli immediately beneath the anterior surface are arranged parallel with it. In the rest of the bone they radiate from the posterior articular surface toward the other parts of the bone.

Development.—From a *single* centre, which makes its appearance in the second or third, but may not appear until the sixth year. More rarely, the bone is developed by two centres, placed side by side. Ossification is completed about the age of puberty.

Articulations.—With the two condyles of the femur.

Attachment of Muscles.—To *four*—the Rectus, Crureus, Vastus internus, and Vastus externus. These muscles, joined at their insertion, constitute the Quadriceps extensor cruris.

Surface Form.—The external surface of the patella can be seen and felt in front of the knee. In the extended position of the limb the internal border is a little more prominent than the outer, and if the Quadriceps extensor is relaxed the bone can be moved from side to side and appears to be loosely fixed. If the joint is flexed, the patella recedes into the hollow between the condyles of the femur and the upper end of the tibia, and becomes firmly fixed against the femur.

Applied Anatomy.—The main surgical interest about the patella is in connection with *fractures*, which are of common occurrence. They may be produced by muscular action; that is to say, by violent contraction of the Quadriceps extensor while the limb is in a position of semi-flexion, so that the bone is snapped across the condyles; or by direct violence, such as falls on the knee. Most fractures are due to muscular action; in fact, the patella is more often broken by muscular action than is any other bone. In fractures by muscular action the line of fracture is transverse. In fractures by direct force the line of fracture may be oblique, longitudinal, stellate, or the bone variously comminuted. The principal interest in these cases attaches to their treatment. Owing to the wide separation of the fragments, and the difficulty there is in maintaining them in apposition, union takes place by fibrous tissue, and this may subsequently stretch, producing wide separation of the fragments and permanent lameness. Various plans, including opening the joint and suturing the fragments, have been advocated for overcoming this difficulty. In many cases a portion of fascia or capsule gets between the fragments. In such a condition operation is necessary.

In the larger number of cases of fracture of the patella the knee-joint is involved, the cartilage which covers its posterior surface being torn, the synovial membrane lacerated, the lateral fibrous expansions ruptured, and the patellar bursa torn open. In cases of fracture from direct violence, however, this need not necessarily happen, the lesion may involve only the superficial part of the bone; and, as Morris has pointed out, it is an anatomical possibility, in complete fracture, if the lesion involve only the lower and nonarticular part of the bone, for it to take place without injury to the synovial membrane.

The Tibia, or Shin Bone (Figs. 185, 186).

The **tibia** is situated at the front and inner side of the leg, and, excepting the femur, is the longest and largest bone in the skeleton. It is prismoid in form, expanded above, where it enters into the knee-joint, more slightly enlarged below.

In the male its direction is vertical and parallel with the bone of the opposite side; but in the female it has a slightly oblique direction downward and outward, to compensate for the oblique direction of the femur inward. It presents for examination a **shaft** and two **extremities**.

The Proximal or Upper Extremity.—The upper extremity, or **head**, is large, and expanded on each side into two lateral eminences, the **internal** and **external tuberosities** (*condylus medialis* and *condylus lateralis*). Superiorly, each tuberosity presents a smooth, concave surface (*facies articularis superior*), which articulates with a condyle of the femur. The *internal articular surface* is oval in shape and concave from side to side; the *external* one is circular, concave from side to side, but slightly convex from before backward, especially at its posterior part, where it is prolonged on to the posterior surface for a short distance; the central portions of these surfaces articulate with the condyles, while the peripheral portions are overlaid by the semilunar cartilages of the knee. Between the two articular surfaces, and nearer the posterior than the anterior aspect of the bone, is an eminence, the **spine of the tibia** (*eminentia intercondyloidea*); surmounted by a prominent **tubercle** on each side (the *tuberculum intercondyloideum mediale* and the *tuberculum intercondyloideum laterale*), on to the lateral aspect of which

FIG. 187.—Upper surface of right tibia, showing attachment of crucial ligaments and semilunar cartilages.

the facets just described are prolonged; in front and behind the spinous process is a rough depression (*fossa intercondyloidea anterior* and the *fossa intercondyloidea posterior*) for the attachment of the anterior and posterior crucial ligaments and the semilunar fibrocartilages (Fig. 187).

The anterior surfaces of the tuberosities are continuous with one another, forming a single large surface, which is somewhat flattened; it is triangular, broad above, and perforated by large vascular foramina; narrow below, where it terminates in a prominent oblong elevation of large size, the **tubercle of the tibia** (*tuberositas tibiae*); the lower half of this tubercle is rough, for the attachment of the *ligamentum patellae*; the upper half presents a smooth facet supporting, in the recent state, a *bursa* which separates the ligament from the bone. Posteriorly the tuberosities are separated from each other by a shallow depression, the **popliteal notch** (*incisura poplitea*), which gives attachment to part of the posterior crucial ligament and part of the posterior ligament of the knee-joint. The *inner tuberosity* presents posteriorly a deep transverse groove, for the insertion of one of the fasciculi of the tendon of the *Semimembranosus*. Its lateral surface is convex, rough, and prominent, and gives attachment to the internal lateral ligament. The *outer tuberosity* presents posteriorly a flat articular facet (*facies articularis fibularis*), nearly circular in form, directed downward, backward,

and outward, for articulation with the fibula. Its lateral surface is convex and rough, more prominent in front than the internal, and presents a prominent rough eminence, situated on a level with the upper border of the tubercle of the tibia at the junction of its anterior and outer surfaces, for the attachment of the **iliotibial band**. Just below this the Extensor longus digitorum arises, and a slip from the Biceps femoris cruris is attached.

Shaft of the Tibia (*corpus tibiae*).—The shaft of the tibia is of a triangular prismoid form, broad above, gradually decreasing in size to its most slender part, the commencement of its lower fourth; it then enlarges again toward its lower extremity. It presents for examination three borders and three surfaces.

The **anterior border**, the most prominent, is called the **crest of the tibia** (*crista anterior*); it commences above at the tubercle, and terminates below at the anterior margin of the inner malleolus. This border is very prominent in the upper two-thirds of its extent, smooth and rounded below. It presents a very sinuous course, being usually curved outward above and inward below; it gives attachment to the deep fascia of the leg.

The **internal border** (*margo medialis*) is smooth and rounded above and below, but more prominent in the centre; it commences at the back part of the inner tuberosity, and terminates at the posterior border of the internal malleolus; its upper part gives attachment to the internal lateral ligament of the knee to the extent of about two inches, and to some fibres of the Popliteus muscle, and its middle third to some fibres of origin of the Soleus and Flexor longus digitorum muscles.

The **external border** (*crista interossea*), or **interosseous ridge**, is thin and prominent, especially its central part, and gives attachment to the interosseous membrane; it commences above in front of the fibular articular facet, and bifurcates below, to form the boundaries of a triangular rough surface, for the attachment of the interosseous ligament connecting the tibia and fibula.

The **internal surface** (*facies medialis*) is smooth, convex, and broader above than below; its upper third, directed forward and inward, is covered by the aponeurosis derived from the tendon of the Sartorius, and by the tendons of the Gracilis and Semitendinosus, all of which are inserted nearly as far forward as the anterior border; in the rest of its extent it is subcutaneous.

The **external surface** (*facies lateralis*) is narrower than the internal; its upper two-thirds presents a shallow groove for the origin of the Tibialis anticus muscle; its lower third is smooth, convex, curves gradually forward to the anterior aspect of the bone, and is covered from within outward by the tendons of the following muscles: Tibialis anticus, Extensor proprius hallucis, Extensor longus digitorum.

The **posterior surface** (*facies posterior*) (Fig. 186) presents, at its upper part, a prominent ridge, the **oblique line of the tibia** (*linea poplitea*), which extends from the back part of the articular facet for the fibula obliquely downward, to the internal border, at the junction of its upper and middle thirds. It marks the lower limit for the insertion of the Popliteus muscle, and serves for the attachment of the popliteal fascia and part of the Soleus, Flexor longus digitorum, and Tibialis posticus muscles; the triangular concave surface, above and to the inner side of this line, gives attachment to the Popliteus muscle. The middle third of the posterior surface is divided by a vertical ridge into two lateral halves; the ridge is well marked at its commencement at the oblique line, but becomes gradually indistinct below; the inner and broader half gives origin to the Flexor longus digitorum, the outer and narrower to part of the Tibialis posticus. The remaining part of the bone presents a smooth surface covered by the Tibialis posticus, Flexor longus digitorum, and Flexor longus hallucis muscles. Immediately below the oblique line is the **nutrient foramen**, which is large and directed obliquely downward. It is the opening of the nutrient canal, which is directed toward the ankle.

The Distal or Lower Extremity.—The lower extremity, much smaller than the upper, presents five surfaces; it is prolonged downward, on its inner side, to a strong process, the **internal malleolus** (*malleolus medialis*).

The **inferior surface** (*facies articularis inferior*) of the bone is quadrilateral, and smooth for articulation with the astragalus. This surface is concave from before backward, and broader in front than behind. It is traversed from before backward by a slight elevation, separating two lateral depressions. It is narrow internally, where the articular surface becomes continuous with that on the inner malleolus.

The **anterior surface** of the lower extremity is smooth and rounded above, and covered by the tendons of the Extensor muscles of the toes; its lower margin presents a rough transverse depression, for the attachment of the anterior ligament of the ankle-joint.

The **posterior surface** presents a superficial groove directed obliquely downward and inward, continuous with a similar groove on the posterior surface of the astragalus, and serving for the passage of the tendon of the Flexor longus hallucis.

The **external surface** presents a triangular rough depression for the attachment of the interior interosseous ligament, connecting it with the fibula; the lower part of this depression, the *incisura fibularis*, is smooth, covered with cartilage in the recent state, and articulates with the fibula. This surface is bounded by two prominent borders, continuous above with the interosseous ridge; they afford attachment to the anterior inferior and posterior inferior tibiofibular ligaments.

The **internal surface** of the lower extremity is prolonged downward to form a strong pyramidal process, flattened from without inward—the **internal malleolus** (*malleolus medialis*). The *inner surface* of this process is convex and subcutaneous; its *outer surface* is smooth and slightly concave, and articulates with the astragalus; its *anterior border* is rough, for the attachment of the anterior fibres of the internal lateral or deltoid ligament; its *posterior border* presents a broad and deep groove (*sulcus malleolaris*), directed obliquely downward and inward, which is occasionally double; this groove transmits the tendons of the Tibialis posticus and Flexor longus digitorum muscles. The *summit* of the internal malleolus is marked by a rough depression behind, for the attachment of the internal lateral ligaments of the ankle-joint.

Structure.—Like that of the other long bones. At the junction of the middle and lower third, where the bone is smallest, the wall of the shaft is thicker than in other parts, in order to compensate for the smallness of the calibre of the bone.

Development.—From three centres (Fig. 188), one for the shaft and one for each extremity. Ossification commences in the centre of the shaft about the seventh week, and gradually extends toward either extremity. The centre for the upper epiphysis appears before or shortly after birth; it is flattened in form, and has a thin, tongue-shaped process in front which forms the tubercle. That for the lower epiphysis appears in the second year. The lower epiphysis joins the shaft at about the eighteenth, and the upper one about the twentieth year. Two additional centres occasionally exist—one for the tongue-shaped process of the upper epiphysis, which forms the tubercle, and one for the inner malleolus.

FIG. 188.—Plan of the development of the tibia. From three centres.

Articulations.—With *three* bones—the femur, fibula, and astragalus.

Attachment of Muscles.—To *twelve*: To the inner tuberosity, the Semimembranosus; to the outer tuberosity, the Tibialis anticus and Extensor longus digitorum and Biceps femoris, to the shaft, its internal surface, the Sartorius, Gracilis, and Semitendinosus; to its external surface, the Tibialis anticus; to its posterior surface, the Popliteus, Soleus, Flexor longus digitorum, and Tibialis posticus; to the tubercle, the ligamentum patellae, by which the Quadriceps extensor muscle is inserted into the tibia. In addition to these muscles, the Tensor fasciae femoris is inserted indirectly into the tibia, through the iliotibial band, and the Peroneus longus occasionally derives a few fibres of origin from the outer tuberosity.

Surface Form.—A considerable portion of the tibia is subcutaneous and easily felt. At the upper extremity the tuberosities are to be recognized just below the knee. The internal one is broad and smooth, and merges into the subcutaneous surface of the shaft below. The external one is narrower and more prominent, and on it, about midway between the apex of the patella and the head of the fibula, may be felt a prominent **tubercle** for the insertion of the iliotibial band. In front of the upper end of the bone, between the tuberosities, is the tubercle of the tibia, forming an oval eminence which is continuous below with the anterior border or crest of the bone. This border can be felt, forming the prominence of the shin, in the upper two-thirds of its extent as a sharp and sinuous ridge, curved outward above and inward below. In the lower third of the leg the border disappears, and the bone is concealed by the tendons of the muscles on the front of the leg. Internal to the anterior border is to be felt the broad internal surface of the tibia, slightly encroached upon by the muscles in front and behind. It commences above at the wide expanded inner tuberosity, and terminates below at the internal malleolus. The internal malleolus is a broad prominence situated on a higher level and somewhat farther forward than the external malleolus. It overhangs the inner border of the arch of the foot. Its anterior border is nearly straight; its posterior border presents a sharp edge which forms the inner margin of the groove for the tendon of the Tibialis posticus muscle.

The Fibula, or Calf Bone (Figs. 185, 186).

The **fibula** is situated at the outer side of the leg. It is the smaller of the two bones, and, in proportion to its length, the most slender of all the long bones; it is placed on the outer side of the tibia, with which it is connected above and below. Its upper extremity is small, placed toward the back of the head of the tibia and below the level of the knee-joint, and excluded from its formation; the lower extremity inclines a little forward, so as to be on a plane anterior to that of the upper end, projects below the tibia, and forms the outer ankle. It presents for examination a shaft and two extremities.

The Proximal or Upper Extremity.—The upper extremity, or head (*capitulum fibulae*), is of an irregular quadrate form, presenting above a flattened articular facet, directed upward, forward, and inward, for articulation with a corresponding facet on the external tuberosity of the tibia. On the outer side is a thick and rough prominence, continued behind into a pointed eminence, the **styloid process of the fibula** (*apex capituli fibulae*), which projects upward from the posterior part of the head. The *prominence* gives attachment to the tendon of the Biceps femoris muscle and to the long external lateral ligament of the knee, the ligament dividing the tendon into two parts. The *summit* of the styloid process gives attachment to the short external lateral ligament. The remaining part of the circumference of the head is rough, for the attachment of muscles and ligaments. It presents in front a tubercle for the origin of the upper and anterior part of the Peroneus longus, and the adjacent surface gives attachment to the anterior superior tibiofibular ligament; and behind, another tubercle for the attachment of the posterior superior tibiofibular ligament and the upper fibres of origin of the Soleus muscle.

The Shaft (*corpus fibulae*).—The shaft presents four borders—the antero-external, the antero-internal, the postero-external, and the postero-internal; and four surfaces—anterior, posterior, internal, and external.

The **antero-external border** (*crista anterior*) commences above in front of the head, runs vertically downward to a little below the middle of the bone, and then,

curving somewhat outward, bifurcates so as to embrace the triangular subcutaneous surface immediately above the outer surface of the external malleolus. This border gives attachment to an intermuscular septum, which separates the Extensor muscles on the anterior surface of the leg from the Peroneus longus and brevis muscles on the outer surface.

The **antero-internal border** (*crista interossea*), or **interosseous ridge**, is situated close to the inner side of the preceding, and runs nearly parallel with it in the upper third of its extent, but diverges from it so as to include a broader space in the lower two-thirds. It commences above, just beneath the head of the bone (sometimes it is quite indistinct for about an inch below the head), and terminates below at the apex of a rough triangular surface immediately above the articular facet of the external malleolus. It serves for the attachment of the interosseous membrane, which separates the Extensor muscles in front from the Flexor muscles behind.

The **postero-external border** (*crista lateralis*) is prominent; it commences above at the base of the styloid process, and terminates below in the posterior border of the outer malleolus. It is directed outward, above, backward in the middle of its course, backward and a little inward below, and gives attachment to an aponeurosis which separates the Peronei muscles on the outer surface of the shaft from the Flexor muscles on its posterior surface.

The **postero-internal border** (*crista medialis*) sometimes called the **oblique line**, commences above at the inner side of the head, and terminates by becoming continuous with the interosseous ridge at the lower fourth of the bone. It is well marked and prominent at the upper and middle parts of the bone. It gives attachment to an aponeurosis which separates the Tibialis posticus from the Soleus above and the Flexor longus hallucis below.

The **anterior surface** (*facies anterior*) is the interval between the antero-external and antero-internal borders. It is extremely narrow and flat in the upper third of its extent, broader and grooved longitudinally in its lower third; it serves for the origin of three muscles, the Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis.

The **external surface** (*facies lateralis*) is the space between the antero-external and postero-external borders. It is much broader than the preceding, and often deeply grooved, is directed outward in the upper two-thirds of its course, backward in the lower third, where it is continuous with the posterior border of the external malleolus. This surface is completely occupied by the Peroneus longus and brevis muscles.

The **internal surface** (*facies medialis*) is the interval included between the antero-internal and the postero-internal borders. It is directed inward, and is grooved for the origin of the Tibialis posticus muscle.

The **posterior surface** (*facies posterior*) is the space included between the postero-external and the postero-internal borders; it is continuous below with the rough triangular surface above the articular facet of the outer malleolus; it is directed backward above, backward and inward at its middle, directly inward below. Its upper third is rough, for the origin of the Soleus muscle; its lower part presents a triangular rough surface, connected to the tibia by a strong interosseous ligament, and between these two points the entire surface is covered by the fibres of origin of the Flexor longus hallucis muscle. At about the middle of this surface is the **nutrient foramen**. It opens into the **nutrient canal**, which is directed downward.

The Distal or Lower Extremity.—The lower extremity, or **external malleolus** (*malleolus lateralis*), is of a pyramidal form, somewhat flattened from without inward, and is longer, and descends lower than the internal malleolus. Its **external surface** is convex, subcutaneous, and continuous with the triangular (also subcutaneous) surface on the outer side of the shaft. The **internal surface** presents in front a smooth triangular facet (*facies articularis malleoli*), broader above than

below, and convex from above downward, which articulates with a corresponding surface on the outer side of the astragalus. Behind and beneath the articular surface is a rough depression which gives attachment to the posterior fasciculus of the external lateral ligament of the ankle. The *anterior border* is thick and rough, and marked below by a depression for the attachment of the anterior fasciculus of the external lateral ligament. The *posterior border* is broad and marked by a shallow groove (*sulcus malleolaris*), for the passage of the tendons of the Peroneus longus and brevis muscles. The *apex* is rounded, and gives attachment to the middle fasciculus of the external lateral ligament.

FIG. 189.—Lower extremity of right fibula. Internal aspect.

FIG. 190.—Plan of the development of the fibula. From three centres.

In order to distinguish the side to which the bone belongs, hold it with the lower extremity downward and the broad groove for the Peronei tendons backward—*i. e.*, toward the holder; the triangular subcutaneous surface will then be directed to the side to which the bone belongs.

Development.—From *three* centres (Fig. 190)—one for the shaft and one for each extremity. Ossification commences in the shaft about the eighth week of fetal life, a little later than in the tibia, and extends gradually toward the extremities. At birth both ends are cartilaginous. Ossification commences in the lower end in the second year, and in the upper one about the fourth year. The lower epiphysis, the first in which ossification commences, becomes united to the shaft about the twentieth year; the upper epiphysis joins about the twenty-fifth year. Ossification appearing first in the lower epiphysis is contrary to the rule which prevails with regard to the commencement of ossification in epiphyses—*viz.*, that epiphysis toward which the nutrient artery is directed commences to ossify last; but it follows the rule which prevails with regard to the union of epiphyses, by uniting first.

Articulations.—With *two* bones: the tibia and astragalus.

Attachment of Muscles.—To *nine*: To the head, the Biceps femoris, Soleus, and Peroneus longus; to the shaft, its anterior surface, the Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis; to the internal surface, the Tibialis posticus; to the posterior surface, the Soleus and Flexor longus hallucis, to the external surface, the Peroneus longus and brevis.

Surface Form.—The only parts of the fibula which may be felt are the head and the lower part of the external surface of the shaft and the external malleolus. The head may be seen and felt behind and to the outer side of the outer tuberosity of the tibia. It presents a small, prominent triangular eminence slightly above the level of the tubercle of the tibia. The exter-

nal malleolus presents a narrow elongated prominence, situated on a plane posterior to the internal malleolus and reaching to a lower level. From it may be traced the lower third or half of the external surface of the shaft of the bone in the interval between the *Peroneus tertius* in front and the other two *Peronei* tendons behind.

Applied Anatomy.—In *fractures of the bones of the leg* both bones are usually fractured, but either bone may be broken separately, the fibula more frequently than the tibia. Fracture of both bones may be caused either by direct or indirect violence. When it occurs from indirect force the fracture in the tibia is usually at the junction of the middle and lower third of the bone. Many causes conduce to render this the weakest part of the bone. The fracture of the fibula is usually at rather a higher level. These fractures present great variety, both as regards their direction and condition. They may be oblique, transverse, longitudinal, or spiral. When oblique, they are usually the result of indirect violence, and the direction of the fracture is from behind, downward, forward, and inward in many cases, but may be downward and outward or downward and backward. When transverse, the fracture is often at the upper part of the bone, and is the result of direct violence. The spiral fracture usually commences as a vertical fissure, involving the ankle-joint, and is associated with fracture of the fibula higher up. It is the result of torsion, from twisting of the body while the foot is fixed.

Fractures of the tibia alone are almost always the result of direct violence, except where the malleolus is broken off by twists of the foot. Fractures of the fibula alone may arise from indirect or direct force, those of the lower end being usually the result of the former, and those higher up being caused by a direct blow on the part.

The tibia and fibula, like the femur, are frequently the seat of *acute osteomyelitis*. *Tuberculous abscess* is more frequently met with in the cancellous tissue of the head and lower end of the tibia than in any other bone of the body. The abscess is of small size, very chronic, and probably the result of tuberculous osteitis in the highly vascular growing tissue at the end of the shaft near the epiphyseal cartilage in the young subject. Such an abscess in bone is called *Brodie's abscess*.

The tibia is the bone which is most frequently and most extensively distorted in *rhachitis*. It gives way at the junction of the middle and lower third, its weakest part, and presents a curve forward and outward. *Bow-leg* is due to outward curvature of the femur, tibia, and fibula, the bend being about the junction of the shafts and lower extremities.

THE FOOT (Figs. 191, 192).

The skeleton of the foot consists of three divisions—the **tarsus**, **metatarsus**, and **phalanges**.

The Tarsus (*ossa tarsi*).—The bones of the tarsus are *seven* in number—viz., the **calcaneus**, or **os calcis**, **astragalus**, **cuboid**, **scaphoid**, **internal**, **middle**, and **external cuneiform**.

The Calcaneus (*os calcis*) (Fig. 194).—The heel bone is the largest and strongest of the tarsal bones. It is irregularly cuboidal in form, having its long axis directed forward and outward. It is situated at the lower and back part of the foot, serving to transmit the weight of the body to the ground, and forming a strong lever for the muscles of the calf. It presents for examination six surfaces—superior, inferior, external, internal, anterior, and posterior.

The **superior surface** is formed, behind, by the upper aspect of that part of the *os calcis* which projects backward to form the heel. It varies in length in different individuals; is convex from side to side, concave from before backward, and corresponds above to a mass of adipose substance placed in front of the *tendo Achillis*. In the middle of the superior surface are two (sometimes three) articular facets, separated by a broad shallow groove (*sulcus calcanei*), which is directed obliquely forward and outward, and is rough for the attachment of the interosseous ligament connecting the astragalus and *os calcis*. When the calcaneus is in contact with the astragalus this groove is converted into a canal (*sinus tarsi*). Of the articular surfaces, the **posterior articular surface** (*facies articularis posterior*) is the larger, and is situated on the body of the bone; it is of an oblong form, wider behind than in front, and convex; it articulates with the posterior facet of the astragalus. The **anterior articular surface** is usually divided into two facets, the anterior of which

FIG. 191.—Bones of the right foot. Dorsal surface.

FIG. 192.—Bones of the right foot. Plantar surface.

(*facies articularis anterior*) supports the head of the astragalus. The more posteriorly situated facet (*facies articularis calcanea media*) articulates with the middle facet on the under surface of the astragalus. The anterior articular surface is supported on a projecting process of bone, called the **lesser process of the calcaneus** (*sustentaculum tali*); it is oblong, concave longitudinally, and sometimes subdivided into two parts, which differ in size and shape. More anteriorly is

seen the upper surface of the **greater process of the calcaneus**, marked by a rough depression for the attachment of numerous ligaments, and a tubercle for the origin of the Extensor brevis digitorum muscle.

The **inferior surface** is narrow, rough, uneven, wider behind than in front, and convex from side to side; it is bounded posteriorly by two tubercles separated by a rough depression; the **external tubercle** (*processus lateralis tuberis calcanei*), small, prominent, and rounded, gives attachment to part of the Abductor minimi digiti; the **internal tubercle** (*processus medialis tuberis calcanei*), broader and larger, for the support of the heel, gives origin, by its prominent inner margin, to the Abductor hallucis, and in front to the Flexor brevis digitorum muscle and plantar fascia; the depression between the tubercles gives origin to the Abductor minimi digiti. The rough surface in front of the tubercles gives attachment to the long plantar ligament and origin to the outer head of the Flexor accessorius muscle; while to a prominent tubercle nearer the anterior part of this surface, as well as to a transverse groove in front of it, is attached the short plantar ligament.

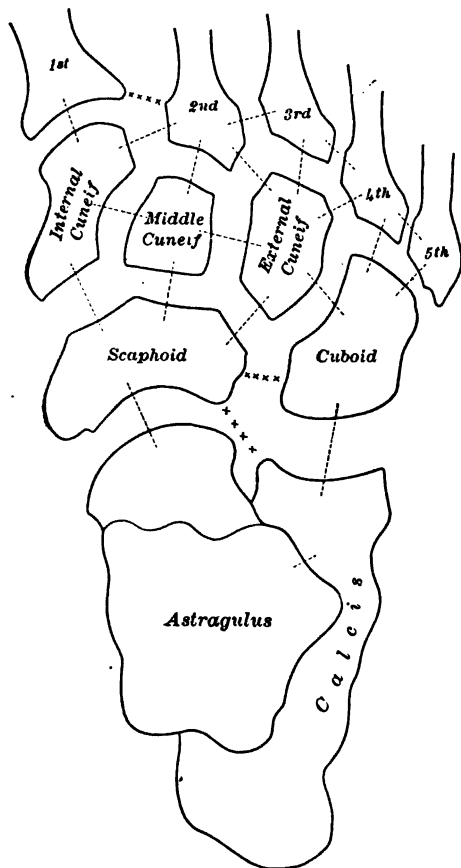

FIG. 193.—Schematic representation of the articulations of the tarsus. Occasional articulations shown by x x x x.

The **external surface** is broad, flat, and almost subcutaneous; it presents near its centre a tubercle, for the attachment of the middle fasciculus of the external lateral ligament. At its upper and anterior part this surface gives attachment to the external calcaneo-astragaloid ligament; and in front of the tubercle it presents a narrow surface marked by two oblique grooves; separated by an elevated ridge which varies much in size in different bones, it is named the **peroneal spine** (*processus trochlearis*), and gives attachment to a fibrous process from the external annular ligament. The *superior groove* transmits the tendon of the Peroneus brevis; the *inferior groove* the tendon of the Peroneus longus.

The **internal surface** is deeply concave; it is directed obliquely downward and forward, and serves for the transmission of the plantar vessels and nerves into the sole of the foot; it affords origin to part of the Flexor accessorius muscle. At its upper and fore part it presents an eminence of bone, the *sustentaculum tali*, which projects horizontally inward, and to it a slip of the tendon of the Tibialis posticus is attached. This process is concave above, and supports the anterior

articular surface of the astragalus; below, it is grooved for the tendon of the Flexor longus hallucis. Its free margin is rough, for the attachment of part of the internal lateral ligament of the ankle-joint.

The **anterior surface** (*facies articularis cuboidea*), of a somewhat triangular form, articulates with the cuboid. It is concave from above downward and outward, and convex in the opposite direction. Its *inner border* gives attachment to the inferior calcaneoscapoid ligament.

FIG. 194.—The left os calcis. A. Postero-external view. B. Antero-internal view.

The **posterior surface** is rough, prominent, convex, and wider below than above. The posterior extremity is the projection of the heel. It is called the **tuberosity** (*tuber calcanei*). Its lower part is rough, for the attachment of the tendo Achillis and the tendon of the Plantaris muscle; its upper part is smooth, and is covered by a bursa which separates the tendons from the bone.

Articulations.—With *two* bones—the astragalus and cuboid.

Attachment of Muscles.—To *eight*, part of the Tibialis posticus, the tendo Achillis, Plantaris, Adductor hallucis, Abductor minimi digiti, Flexor brevis digitorum, Flexor accessorius, and Extensor brevis digitorum.

FIG. 195.—The left astragalus. A. Supero-external view. B. Infero-internal view. C. Inferior view.

The Astragalus, or Ankle Bone (*talus*) (Fig. 195).—The astragalus is the second largest of the tarsal bones. It occupies the middle and upper part of the tarsus, supporting the tibia above, articulating with the malleoli on either side, resting below upon the os calcis, and joined in front to the scaphoid. This bone may

be easily recognized by its large rounded head, by the broad articular facet on its upper convex surface, and by the two articular facets separated by a deep groove on its under concave surface. It presents six surfaces for examination.

The **superior surface** presents, behind, a broad smooth **trochlear surface** (*trochlea tali*) for articulation with the tibia. The trochlea is broader in front than behind, convex from before backward, slightly concave from side to side; in front of it is the upper surface of the neck of the astragalus, rough for the attachment of ligaments.

The **inferior surface** presents two articular facets separated by a deep groove (*sulcus tali*). The groove runs obliquely forward and outward, becoming gradually broader and deeper in front; it corresponds with a similar groove upon the upper surface of the calcaneus, and forms, when articulated with that bone, a canal (*sinus tarsi*), filled up in the recent state by the calcaneo-astragaloid ligament. Of the two articular facets, the **posterior articular facet** (*facies articularis calcanea posterior*) is the larger, of an oblong form and deeply concave from side to side; it rests on the external articular surface of the os calcis; the **anterior articular facet** is shorter and narrower, of an elongated oval form, convex longitudinally, and often subdivided into two by an elevated ridge; of these, the *posterior* (*facies articularis calcanea media*) articulates with the lesser process of the os calcis; the *anterior* (*facies articularis calcanea anterior*), with the upper surface of the inferior calcaneoscaphoid ligament.

The **internal surface** presents at its upper part a pear-shaped articular facet (*facies malleolaris medialis*) for the inner malleolus, continuous above with the trochlear surface; below the articular surface is a rough depression, for the attachment of the deep portion of the internal lateral ligament.

The **external surface** presents a large triangular facet (*facies malleolaris lateralis*), concave from above downward for articulation with the external malleolus; it is continuous above with the trochlear surface; and in front of it is a rough depression for the attachment of the anterior fasciculus of the external lateral ligament of the ankle-joint.

The **anterior surface** (*facies articularis navicularis*) forms the head of the astragalus, is convex and rounded, smooth, of an oval form, and directed obliquely inward and downward; it articulates with the scaphoid. On its under and inner surface is a small facet, continuous in front with the articular surface of the head, and behind with the smaller facet for the os calcis. This rests on the inferior calcaneoscaphoid ligament, being separated from it by the synovial membrane. The head is attached to the rest of the bone by a constricted portion, the **neck of the astragalus** (*collum tali*).

The **posterior surface** is traversed by a groove (*sulcus m. flexoris hallucis longi*), which runs obliquely downward and inward, and transmits the tendon of the Flexor longus hallucis, external to which is the prominent **external tubercle** (*processus posterior tali*), to which the posterior fasciculus of the external lateral ligament is attached. This tubercle is sometimes separated from the rest of the astragalus, and is then known as the **os trigonum**.

To ascertain to which foot the bone belongs, hold it with the broad articular surface upward, and the rounded head forward; the lateral triangular articular surface for the external malleolus will then point to the side to which the bone belongs.

Articulations.—With four bones—tibia, fibula, os calcis, and scaphoid.

The Cuboid (*os cuboideum*) (Fig. 196).—The cuboid is placed on the outer side of the foot, in front of the os calcis, and behind the fourth and fifth metatarsal bones. It is of a pyramidal shape, its base being directed inward, its apex outward. It may be distinguished from the other tarsal bones by the existence

of a deep groove on its under surface, for the tendon of the Peroneus longus muscle. It presents for examination six surfaces, three articular and three nonarticular.

The **nonarticular surfaces** are the dorsal, plantar, and external. The **dorsal surface**, directed upward and outward, is rough, for the attachment of numerous ligaments. The **plantar surface** presents in front a deep groove, the **peroneal groove** (*sulcus m. peronei longi*), which runs obliquely from without, forward and inward; it lodges the tendon of the Peroneus longus, and is bounded behind by a prominent ridge, to which is attached the long calcaneocuboid ligament. The ridge terminates externally in an eminence (*tuberositas ossis cuboidei*), the surface of which presents a convex facet, for articulation with the sesamoid bone of the tendon contained in the groove. The surface of bone behind the groove is rough, for the attachment of the short plantar ligament, a few fibres of origin of the Flexor brevis hallucis, and a fasciculus from the tendon of the Tibialis posticus. The **external surface**, the smallest and narrowest of the three, presents a deep notch formed by the commencement of the peroneal groove.

FIG. 196.—The left cuboid. A. Antero-internal view. B. Postero-external view.

The **articular surfaces** are the posterior, anterior, and internal. The **posterior surface** is smooth, triangular, and concavo-convex, for articulation with the anterior surface of the os calcis. The **anterior surface**, of smaller size, but also irregularly triangular, is divided by a vertical ridge into two facets; the inner one, quadrilateral in form, articulates with the fourth metatarsal bone; the outer one, larger and more triangular, articulates with the fifth metatarsal. The **internal surface** is broad, rough, irregularly quadrilateral, presenting at its middle and upper part a smooth oval facet, for articulation with the external cuneiform bone; and behind this (occasionally) a smaller facet, for articulation with the navicular; it is rough in the rest of its extent, for the attachment of strong interosseous ligaments.

To ascertain to which foot the bone belongs, hold it so that its under surface, marked by the peroneal groove, looks downward, and the large concavo-convex articular surface backward toward the holder: the narrow nonarticular surface, marked by the commencement of the peroneal groove, will point to the side to which the bone belongs.

Articulations.—With four bones—the os calcis, external cuneiform, and the fourth and fifth metatarsal bones; occasionally with the scaphoid.

Attachment of Muscles.—Part of the Flexor brevis hallucis and a slip from the tendon of the Tibialis posticus.

Scaphoid or Navicular Bone (*os naviculare pedis*) (Fig. 197).—The scaphoid is situated at the inner side of the tarsus, between the astragalus behind and the three cuneiform bones in front. It may be distinguished by its form, being concave behind, convex and subdivided into three facets in front.

The **anterior surface**, of an oblong form, is convex from side to side, and subdivided by two ridges into three facets, for articulation with the three cuneiform bones. The **posterior surface** is oval, concave, broader externally than internally,

and articulates with the rounded head of the astragalus. The **dorsal surface** is convex from side to side, and rough for the attachment of ligaments. The **plantar** is irregular, and also rough for the attachment of ligaments. The **internal surface** presents a rounded tubercular eminence, the **tuberosity** (*tuberositas ossis navicularis*), the lower part of which projects, and gives attachment to part of the tendon of the *Tibialis posticus*. The **external surface** is rough and irregular, for the attachment of ligamentous fibres, and occasionally presents a small facet for articulation with the cuboid bone.

FIG. 197.—The left scaphoid. A. Antero-external view. B. Postero-internal view.

To ascertain to which foot the bone belongs, hold it with the concave articular surface backward, and the convex dorsal surface upward; the external surface—i. e., the surface opposite the tubercle—will point to the side to which the bone belongs.

Articulations.—With four bones—astragalus and three cuneiform; occasionally also with the cuboid.

Attachment of Muscles.—Part of the *Tibialis posticus*.

Cuneiform or Wedge Bones.—The cuneiform bones have received their name from their wedge-like shape. They form, with the cuboid, the distal row of the tarsus, being placed between the scaphoid behind, the three innermost metatarsal bones in front, and the cuboid externally. They are called the **first, second, and third**, counting from the inner to the outer side of the foot, and, from their position, **internal, middle, and external**.

Internal or First Cuneiform (*os cuneiforme primum*) (Fig. 198).—The internal cuneiform is the largest of the three. It is situated at the inner side of the foot, between the scaphoid behind and the base of the first metatarsal in front. It may be distinguished from the other

FIG. 198.—The left internal cuneiform. A. Antero-internal view. B. Postero-external view.

two by its large size, and by its not presenting such a distinct wedge-like form. Without the others it may be known by the large, kidney-shaped anterior articulating surface and by the prominence on the inferior or plantar surface for the attachment of the *Tibialis posticus*. It presents for examination six surfaces.

The **internal surface** is subcutaneous, and forms part of the inner border of the foot; it is broad, quadrilateral, and presents at its anterior inferior angle a smooth oval facet, into which the tendon of the *Tibialis anticus* is partially inserted; in the rest of its extent it is rough, for the attachment of ligaments. The **external**

surface is concave, presenting, along its superior and posterior borders, a narrow, reversed, L-shaped surface, for articulation with the middle cuneiform behind and second metatarsal bone in front; in the rest of its extent it is rough, for the attachment of ligaments, and part of the tendon of the Peroneus longus. The **anterior surface**, kidney-shaped, much larger than the posterior, articulates with the metatarsal bone of the great toe. The **posterior surface** is triangular, concave, and articulates with the innermost and largest of the three facets on the anterior surface of the scaphoid. The **plantar surface** is rough, and presents a prominent tuberosity at its back part for the attachment of part of the tendon of the Tibialis posticus. It also gives attachment in front to part of the tendon of the Tibialis anticus. The **dorsal surface** is the narrow-pointed end of the wedge, which is directed upward and outward; it is rough for the attachment of ligaments.

To ascertain to which side the bone belongs, hold it so that its dorsal narrow edge looks upward, and the long, kidney-shaped, articular surface forward; the external surface, marked by its vertical and horizontal articular facets, will point to the side to which it belongs.

Articulations.—With *four* bones: scaphoid, middle cuneiform, first and second metatarsal bones.

Attachment of Muscles.—To *three*—the Tibialis anticus and posticus, and Peroneus longus.

Middle or Second Cuneiform (*os cuneiforme secundum*) (Fig. 199).—The middle cuneiform, the smallest of the three, is of very regular wedge-like form, the broad extremity being placed upward, the narrow end downward. It is situated between

FIG. 199.—The left middle cuneiform. A. Antero-internal view. B. Postero-external view.

the other two bones of the same name, and articulates with the scaphoid behind and the second metatarsal in front. It is smaller than the external cuneiform bone, from which it may be further distinguished by the L-shaped articular facet, which runs around the upper and back part of its inner surface.

The **anterior surface**, triangular in form and narrower than the posterior, articulates with the base of the second metatarsal bone. The **posterior surface**, also triangular, articulates with the scaphoid. The **internal surface** presents an L-shaped articular facet, running along the superior and posterior borders, for articulation with the internal cuneiform, and is rough in the rest of its extent, for the attachment of ligaments. The **external surface** presents posteriorly a smooth facet for articulation with the external cuneiform bone. The **dorsal surface** forms the base of the wedge; it is quadrilateral, broader behind than in front, and rough for the attachment of ligaments. The **plantar surface**, pointed and tubercular, is also rough for ligamentous attachment and for the insertion of a slip from the tendon of the Tibialis posticus.

To ascertain to which foot the bone belongs, hold its superior or dorsal surface upward, the broadest edge being toward the holder; the smooth facet (limited to the posterior border) will then point to the side to which it belongs.

Articulations.—With *four* bones—scaphoid, internal and external cuneiform, and second metatarsal bone.

Attachment of Muscles.—A slip from the tendon of the Tibialis posticus is attached to this bone.

External or Third Cuneiform (*os cuneiforme tertium*) (Fig. 200).—The external cuneiform, intermediate in size between the two preceding, is of a very regular wedge-like form, the broad extremity being placed upward, the narrow end down-

ward. It occupies the centre of the front row of the tarsus, between the middle cuneiform internally, the cuboid externally, the scaphoid behind, and the third metatarsal in front. It is distinguished from the internal cuneiform bone by its more regular wedge-like shape and by the absence of the kidney-shaped articular surface; from the middle cuneiform, by the absence of the L-shaped facet, and by the two articular facets which are present on both its inner and outer surfaces. It has six surfaces for examination.

The **anterior surface**, triangular in form, articulates with the third metatarsal bone. The **posterior surface** articulates with the most external facet of the scaphoid, and is rough below for the attachment of ligamentous fibres. The **internal surface** presents two articular facets, separated by a rough depression; the anterior one, sometimes divided into two, articulates with the outer side of the base of the second metatarsal bone; the posterior one skirts the posterior border and articulates with the middle cuneiform; the rough depression between the two gives attachment to an interosseous ligament. The **external surface** also presents two articular facets, separated by a rough nonarticular surface; the anterior facet, situated at the superior angle of the bone, is small, and articulates with the inner side of the base of the fourth metatarsal; the posterior and larger one articulates with the cuboid; the rough, nonarticular surface serves for the attachment of

FIG. 200.—The left external cuneiform. A. Postero-internal view. B. Antero-external view.

an interosseous ligament. The three facets for articulation with the three metatarsal bones are continuous with one another, and covered by a prolongation of the same cartilage; the facets for articulation with the middle cuneiform and scaphoid are also continuous, but that for articulation with the cuboid is usually separate. The **dorsal surface** is of an oblong square form, its posterior external angle being prolonged backward. The **plantar surface** is an obtuse rounded margin, and serves for the attachment of ligaments and a part of the tendon of the Tibialis posticus, and for part of the fibres of origin of the Flexor brevis hallucis.

To ascertain to which side the bone belongs, hold it with the broad dorsal surface upward, the prolonged edge backward; the separate articular facet for the cuboid will point to the proper side.

Articulations.—With *six* bones—the scaphoid, middle cuneiform, cuboid, and second, third, and fourth metatarsal bones.

Attachment of Muscles.—To *two*—part of the Tibialis posticus, and Flexor brevis hallucis.

The number of tarsal bones may be reduced owing to congenital ankylosis which may occur between the os calcis and cuboid, the os calcis and scaphoid, the os calcis and astragalus, or the astragalus and scaphoid.

The Metatarsal Bones (*ossa metatarsalia*).—The **metatarsal bones** are five in number, and are numbered one to five, in accordance with their position from within outward; they are long bones, and present for examination a shaft and two extremities.

Common Characters.—The shaft (*corpus*) is prismoid in form, tapers gradually from the tarsal to the phalangeal extremity, and is slightly curved longitudinally, so as to be concave below, slightly convex above.

FIG. 201.—The first metatarsal. (Left.)

On the plantar surface of the shaft of each bone is a nutrient foramen corresponding to the nutrient foramen in each metacarpal bone. The **proximal extremity**, or **base** (*basis*), is wedge-shaped, articulating by its terminal surface with the tarsal bones, and by its lateral surfaces with the contiguous metatarsal bones, its dorsal and plantar surfaces being rough for the attachment of ligaments. The **distal extremity**, or **head** (*capitulum*), presents a terminal rounded articular surface, oblong from above downward, and extending farther backward below than above. Its sides are flattened and present a depression, surmounted by a tubercle, for ligamentous attachment. Its

under surface is grooved in the middle line for the passage of the Flexor tendon, and marked on each side by an articular eminence continuous with the terminal articular surface.

FIG. 202.—The second metatarsal. (Left.)

FIG. 203.—The third metatarsal. (Left.)

Peculiar Characters.—The first metatarsal bone, or the metatarsal bone of the great toe (*os metatarsale I*) (Fig. 201), is remarkable for its great thickness, but is the shortest of all the metatarsal bones. The shaft is strong and of well-marked

prismoid form. The **proximal** extremity presents, as a rule, no lateral articular facet, but occasionally on the outer side there is an oval facet by which it articulates with the second metatarsal bones. Its proximal articular surface is of large size and kidney-shaped; it corresponds to the distal extremity of the internal cuneiform; its circumference is grooved, for the tarsometatarsal ligaments, and internally gives attachment to part of the tendon of the *Tibialis anticus* muscle; its inferior angle presents a rough oval prominence, the **tuberosity** (*tuberositas ossis metatarsalis I*), for the insertion of the tendon of the *Peroneus longus*. The head is of large size; on its plantar surface are two grooved facets, over which glide sesamoid bones; the facets are separated by a smooth elevated ridge.

This bone is known by the single kidney-shaped articular surface on its base, the deeply grooved appearance of the plantar surface of its head, and its great thickness relatively to its length. When it is placed in its natural position, the concave border of the kidney-shaped articular surface on its base points to the side to which the bone belongs.

Attachment of Muscles.—To *three*—part of the *Tibialis anticus*, the *Peroneus longus*, and the *First dorsal interosseous*.

The **second metatarsal** (*os metatarsale II*) (Fig. 202) is the longest and largest of the remaining metatarsal bones, being prolonged backward into the recess formed between the three cuneiform bones. Its *tarsal extremity* is broad above, narrow and rough below. It presents four articular surfaces—one behind, of a triangular form, for articulation with the middle cuneiform; one at the upper part of its internal lateral surface, for articulation with the internal cuneiform; and two on its external lateral surface—an upper and a lower, separated by a rough nonarticular interval. Each of these articular surfaces is divided by a vertical ridge into two facets, thus making four facets; the two anterior of these articulate with the third metatarsal; the two posterior (sometimes continuous) with the external cuneiform. In addition to these articular surfaces there is occasionally a fifth when this bone articulates with the first metatarsal bone. It is oval in shape, and is situated on the inner side of the shaft near the base.

The facets on the tarsal extremity of the second metatarsal bone serve at once to distinguish it from the rest, and to indicate the foot to which it belongs; there being one facet at the upper angle of the internal surface, and two facets, each subdivided into two parts, on the external surface, pointing to the side to which the bone belongs. The fact that the two posterior subdivisions of these external facets sometimes run into one should not be forgotten.

Attachment of Muscles.—To *four*—the *Adductor obliquus hallucis*, *First* and *Second dorsal interossei*, and a slip from the tendon of the *Tibialis posticus*; occasionally also a slip from the *Peroneus longus*.

The **third metatarsal** (*os metatarsale III*) (Fig. 203) articulates proximally, by means of a triangular smooth surface, with the external cuneiform; on its inner side, by two facets, with the second metatarsal; and on its outer side, by a single facet, with the fourth metatarsal. The latter facet is of circular form and situated at the upper angle of the base.

The third metatarsal is known by possessing at its tarsal end two undivided facets on the inner side, and a single facet on the outer. This distinguishes it from the second metatarsal, in which the two facets, found on one side of its tarsal end, are each subdivided into two. The single facet (when the bone is put in its natural position) is on the side to which the bone belongs.

Attachment of Muscles.—To *five*—*Adductor obliquus hallucis*, *Second* and *Third dorsal* and *First plantar interossei*, and a slip from the tendon of the *Tibialis posticus*.

The **fourth metatarsal** (*os metatarsale IV*) (Fig. 204) is smaller in size than the preceding; its *tarsal extremity* presents a terminal quadrilateral surface, for articulation with the cuboid; a smooth facet on the inner side, divided by a ridge into an anterior portion for articulation with the third metatarsal, and a posterior

portion for articulation with the external cuneiform; on the outer side a single facet, for articulation with the fifth metatarsal.

The fourth metatarsal is known by its having a single facet on either side of the tarsal extremity, that on the inner side being divided into two parts. If this subdivision be not recognizable, the fact that its tarsal end is bent somewhat outward will indicate the side to which it belongs.

Attachment of Muscles.—To *five*—Adductor obliquus hallucis, Third and Fourth dorsal, and Second plantar interossei, and a slip from the tendon of the Tibialis posticus.

The **fifth metatarsal bone**, or the **metatarsal bone of the little toe** (*os metatarsale V*) (Fig. 205), is recognized by the **tubercle** (*tuberositas ossis metatarsalis V*) on the outer side of its base. It articulates behind, by a triangular surface cut obliquely from without inward, with the cuboid, and internally with the fourth metatarsal.

FIG. 204.—The fourth metatarsal. (Left.)

FIG. 205.—The fifth metatarsal. (Left.)

The projection on the outer side of this bone at its tarsal end at once distinguishes it from the others, and points to the side to which it belongs.

Attachment of Muscles.—To *six*—the Peroneus brevis, Peroneus tertius, Flexor brevis minimi digiti, Adductor transversus hallucis, Fourth dorsal, and Third plantar interossei.

Articulations.—Each bone articulates with the tarsal bones by one extremity (proximal), and by the other (distal) extremity with the first row of phalanges. The number of tarsal bones with which each metatarsal articulates is one for the first, three for the second, one for the third, two for the fourth, and one for the fifth.

The Phalanges of the Foot (*Phalanges Digitorum Pedis*).

The **phalanges** of the foot, both in number and general arrangement, resemble those in the hand; there being two in the great toe and three in each of the other toes. The nutritive foramina correspond to those in the phalanges of the hand.

The **first** or **proximal phalanx** (*phalanx prima*) resembles closely the corresponding bone of the hand. The **shaft** also is compressed from side to side, convex above, concave below. The **proximal extremity** is concave; and the **distal extremity** presents a trochlear surface, for articulation with the second phalanx.

The **second phalanx** (*phalanx secunda*) is remarkably small and short, but rather broader than the first phalanx.

The **ungual or distal phalanx** (*phalanx tertia*) in form resembles the bone of the corresponding finger, but is smaller, flattened from above downward, presenting a broad base for articulation with the second phalanx, and an expanded extremity for the support of the nail and end of the toe.

FIG. 206.—Plan of the development of the foot.

Articulation.—The first row, with the metatarsal bones behind and second phalanges in front; the second row of the four outer toes, with the first and third phalanges; of the great toe, with the first phalanx; the third row of the four outer toes, with the second phalanges.

Attachment of Muscles.—To the first phalanges: Great toe, *five* muscles—innermost tendon of Extensor brevis digitorum, Abductor hallucis, Adductor obliquus hallucis, Flexor brevis hallucis, Adductor transversus hallucis. Second toe, *three* muscles—First and Second dorsal interosseous and First lumbrical. Third toe, *three* muscles—Third dorsal and First plantar interosseous and Second lumbrical. Fourth toe, *three* muscles—Fourth dorsal and Second plantar interosseous and Third lumbrical. Fifth toe, *four* muscles—Flexor brevis minimi digiti, Abductor minimi digiti, and Third plantar interosseous, and Fourth lumbrical. Second phalanges: Great toe—Extensor longus hallucis, Flexor longus hallucis. Other toes—Flexor brevis digitorum, one slip of the common tendon of the Extensor longus and brevis digitorum.¹ Third phalanges: Two slips from the common tendon of the Extensor longus and Extensor brevis digitorum, and the Flexor longus digitorum.

¹ Except the second phalanx of the fifth toe, which receives no slip from the Extensor brevis digitorum.

Development of the Foot (Fig. 206).

The **tarsal bones** are each developed from a *single* centre, excepting the *os calcis*, which has an epiphysis for its posterior extremity. The centres make their appearance in the following order: *os calcis*, at the sixth month of fetal life; *astragalus*, about the seventh month; *cuboid*, at the ninth month; *external cuneiform*, during the first year; *internal cuneiform*, in the third year; *middle cuneiform* and *scaphoid*, in the fourth year. The epiphysis for the posterior tuberosity of the *os calcis* appears at the tenth year, and unites with the rest of the bone soon after puberty. When this part remains as a separate bone, it is called the *os trigonum*.

The **metatarsal bones** are each developed from *two* centres—one for the shaft and *one* for the digital extremity in the four outer metatarsal; *one* for the shaft and *one* for the base in the metatarsal bone of the great toe.¹ Ossification commences in the centre of the shaft about the ninth week, and extends toward either extremity. The centre in the proximal end of the first metatarsal bone appears about the third year, the centre in the distal end of the other bones between the fifth and eighth years; they unite with the shaft between the eighteenth and twentieth years.

The **phalanges** are developed from *two* centres for each bone—one for the shaft and *one* for the proximal extremity. The centre for the shaft appears about the tenth week, that for the epiphysis between the fourth and tenth years; they join the shaft about the eighteenth year.

Construction of the Foot as a Whole (Figs. 207, 208).

The **foot** is constructed on the same principles as the hand, but modified to form a firm basis of support for the rest of the body when in the erect position. It is more solidly constructed, and its component parts are less movable on each other than in the hand. This is especially the case with the great toe, which has to assist in supporting the body, and is therefore constructed with greater solidity; it lies parallel with the other toes, and has a very limited degree of mobility, whereas the thumb, which is occupied in numerous and varied movements, is constructed in such a manner as to permit of great mobility. Its metacarpal bone is directed away from the others, so as to form an acute angle with the second, and it enjoys a considerable range of motion at its articulation with the carpus. The foot is placed at right angles to the leg—a position which is almost peculiar to man, and has relation to the erect position which he maintains. In order to allow of its supporting the weight of the whole body in this position with the least expenditure of material, it is constructed in the form of an arch. This **antero-posterior** or **longitudinal arch** is made up of two unequal limbs. The hinder one, which is made up of the *os calcis* and the posterior part of the *astragalus*, is about half the length of the anterior limb, and measures about three inches. The anterior limb consists of the rest of the tarsal and the metatarsal bones, and measures about seven inches. It may be said to consist of two parts, an inner segment made up of the head of the *astragalus*, the *scaphoid*, the three *cuneiform*, and the three inner metatarsal bones; and an outer segment composed of the *os calcis*, the *cuboid*, and the two outer metatarsal bones. The summit of the arch is at the superior articular surface of the *astragalus*; and its two extremities—that is to say, the two piers on which the arch rests in standing—are the tubercles on the under surface of the *os calcis* posteriorly, and the heads of the metatarsal bones anteriorly. The weakest part of the arch is the joint between the *astragalus* and *scaphoid*; and here it is more liable to yield in those who are overweighted, and in those in whom the ligaments which complete and preserve the arch are relaxed. This weak point in the arch is braced on its concave surface by the *inferior calcaneoscaphoid ligament*, which is more elastic than most other ligaments, and thus allows the arch to yield from jars or shocks applied to the anterior portion of the foot and quickly restores it to its pristine condition. This

¹ As was noted in the first metacarpal bone, so in the first metatarsal, there is often to be observed a tendency to the formation of a second epiphysis in the distal extremity.

ligament is supported internally by blending with the deltoid ligament, and inferiorly by the tendon of the *Tibialis posticus* muscle, which is spread out into a fan-shaped insertion, and prevents undue tension of the ligament or such an amount of stretching as would permanently elongate it.

In addition to this longitudinal arch the foot presents a **transverse arch**, at the anterior part of the tarsus and hinder part of the metatarsus. This, however, can scarcely be described as a true arch, but presents more the character of a half-dome. The inner border of the central portion of the longitudinal arch is elevated

FIG. 207.—Skeleton of the foot, internal border. (Poirier and Charpy.)

from the ground, and from this point the bones arch over to the outer border, which is in contact with the ground, and, assisted by the longitudinal arch, produce a sort of rounded niche on the inner side of the foot, which gives the appearance of a transverse as well as a longitudinal arch.

The line of the foot, from the point of the heel to the toes, is not quite straight, but is directed a little outward, so that the inner border is a little convex and the outer border concave. This disposition of the bones becomes more marked when the longitudinal arch of the foot is lost, as in the condition known under the name of "flat-foot."

FIG. 208.—Skeleton of the foot, external border. (Poirier and Charpy.)

Surface Form.—On the dorsum of the foot the individual bones are not to be distinguished with the exception of the head of the astragalus, which forms a rounded projection in front of the ankle-joint when the foot is forcibly extended. The whole surface forms a smooth convex outline, the summit of which is the ridge formed by the head of the astragalus, the scaphoid, the middle cuneiform, and the second metatarsal bones; from this it gradually inclines outward and more rapidly inward. On the inner side of the foot, the internal tuberosity of the *os calcis* and the ridge separating the inner from the posterior surface of the bone may be felt most posteriorly. In front of this, and below the internal malleolus, may be felt the projection of the *sustentaculum tali*. Passing forward is the well-marked tuberosity of the scaphoid bone, situated about an inch or an inch and a quarter in front of the internal malleolus. Further toward the front, the ridge formed by the base of the first metatarsal bone can be obscurely felt, and from this the shaft of the bone can be traced to the expanded head articulating with the base

of the first phalanx of the great toe. Immediately beneath the base of this phalanx, the internal sesamoid bone is to be felt. Lastly, the expanded ends of the bones forming the last joint of the great toe are to be felt. On the outer side of the foot the most posterior bony point is the external tubercle of the os calcis, with the ridge separating the posterior from the outer surface of the bone. In front of this the greater part of the external surface of the os calcis is subcutaneous; on it, below and in front of the external malleolus, may be felt the peroneal spine when this is present. Farther forward, the base of the fifth metatarsal bone forms a prominent and well-defined landmark, and in front of this the shaft of the bone, with its expanded head, and the base of the first phalanx may be defined. The sole of the foot is almost entirely covered by soft parts, so that but few bony parts are to be made out, and these somewhat obscurely. The hinder part of the under surface of the os calcis and the heads of the metatarsal bones, with the exception of the first, which is concealed by the sesamoid bones, may be recognized.

Applied Anatomy.—Considering the injuries to which the foot is subjected, it is surprising how seldom the tarsal bones are fractured. This is no doubt due to the fact that the tarsus is composed of a number of bones, articulated by a considerable extent of surface and joined together by very strong ligaments, which serve to mitigate the intensity of violence applied to this part of the body. When *fracture* does occur, these bones, being composed for the most part of a soft cancellous structure, covered only by a thin shell of compact tissue, are often extensively comminuted, especially as most of the fractures are produced by direct violence. As the bones have only a very scanty amount of soft parts over them, fractures are very often compound, and amputation is frequently necessary.

FIG. 209.—Line of Chopart's amputation. (Poirier.)

FIG. 210.—Line of Lisfranc's amputation. (Poirier.)

When fracture occurs in the *anterior group of tarsal bones*, it is almost invariably the result of direct violence; but fractures of the posterior group, that is, of the *calcaneum* and *astragalus*, are most frequently produced by falls from a height on to the feet; though *fracture of the os calcis* may be caused by direct violence or by muscular action. The posterior part of the bone, that is, the part behind the articular surfaces, is almost always the seat of the fracture, though some few cases of *fracture of the sustentaculum tali* and of vertical fracture between the two articulating facets have been recorded. The neck of the astragalus, being the weakest part of the bone, is most frequently fractured, though fractures may occur in any part and almost in any direction, either associated or not with fracture of other bones.

In cases of *club-foot*, especially in congenital cases, the bones of the tarsus become altered in shape and size, and displaced from their proper positions. This is especially the case in *congenital equinovarus*, in which the astragalus, particularly about the head, becomes twisted and atrophied, and a similar condition may be present in the other bones, more especially the scaphoid. The tarsal bones are peculiarly liable to become the seat of *tuberculous caries*, and this condition may arise after comparatively trivial injuries. There are several reasons to account for this. They are composed of a delicate cancellated structure, surrounded by intricate synovial membranes. They are situated at the farthest point from the central organ of the circulation and exposed to vicissitudes of temperature; and, moreover, on their dorsal surface are thinly clad with soft parts which have but a scanty blood-supply. And finally, after slight injuries, they are not maintained in a condition of rest to the same extent as structures suffering from similar injuries in some other parts of the body. *Caries* of the calcaneus or astragalus may remain limited to the one bone for a long period, but when one of the other bones is affected, the remainder frequently become involved, in consequence of the disease spreading through the large and complicated synovial membrane which is more or less common to these bones.

Amputation of the whole or a part of the foot is frequently required either for injury or disease. The principal amputations are as follows: (1) *Syme's amputation* at the ankle-joint by a heel-flap, with the removal of the malleoli and a thin slice from the lower end of the tibia. (2) *Roux's amputation* at the ankle-joint by a large internal flap. (3) *Pirogoff's amputation*: removal of the

whole of the tarsal bones, except the posterior part of the os calcis. A thin slice is sawed from the tibia and fibula, including the two malleoli. The sawed surface of the os calcis is then turned up and united to the similar surface of the tibia. (4) *Subastragaloid amputation*: removal of the foot below the astragalus through the joint between it and the os calcis. This operation has been modified by *Hancock*, who leaves the posterior third of the os calcis and turns it up against the denuded surface of the astragalus. This latter operation is of doubtful utility and is rarely performed. (5) *Chopart's* or *mediotarsal*: removal of the anterior part of the foot with all the tarsal bones except the os calcis and astragalus; disarticulation being effected through the astragaloscaphoid and calcaneocuboid joints. (6) *Lisfranc's amputation* of the anterior part of the foot through the tarsometatarsal joints. This was modified by *Hey*, who disarticulated through the joints of the four outer metatarsal bones with the tarsus, and sawed off the projecting internal cuneiform; and by *Skey*, who sawed off the base of the second metatarsal bone and disarticulated the others.

The bones of the tarsus occasionally require removal individually. This is especially the case with the astragalus and os calcis for disease limited to the one bone, or again the astragalus may require *excision* in cases of subastragaloid dislocation. In cases of inveterate *talipes* the head of the astragalus and greater process of the os calcis is often removed, sometimes the scaphoid is also taken out. Finally, *Mikulicz* and *Watson* have devised operations for the removal of more extensive portions of the tarsus. *Mikulicz's operation* consists in the removal of the os calcis and astragalus, along with the articular surfaces of the tibia and fibula, and also of the scaphoid and cuboid. The remaining portion of the tarsus is then brought into contact with the sawed surfaces of the tibia and fibula, and fixed there. The result is a position of the shortened foot resembling *talipes equinus*. *Watson's operation* is adapted to those cases where the disease is confined to the anterior tarsal bones. By two lateral incisions he saws through the bases of the metatarsal bones in front and opens up the joints between the scaphoid and astragalus, and the cuboid and os calcis, and removes the intervening bones.

Fractures of the metatarsal bones and phalanges are nearly always due to direct violence, and in many cases the injury is the result of severe crushing accidents, necessitating amputation. The metatarsal bones, and especially the metatarsal bone of the great toe are frequently diseased, either in tuberculous subjects or in *perforating ulcer* of the foot.

Sesamoid Bones (*Ossa Sesamoidea*) (Figs. 211, 212).

These are small rounded masses, cartilaginous in early life, osseous in the adult, which are developed in those tendons which exert a great amount of pressure upon

FIG. 211.—Sesamoid bones of the hand. (Poirier and Charpy.)

FIG. 212.—Sesamoid bones of the foot. (Poirier and Charpy.)

the parts over which they glide. It is said that they are more commonly found in the male than in the female, and in persons of an active muscular habit than in those who are weak and debilitated. They are invested throughout their whole surface by the fibrous tissue of the tendon in which they are found, excepting upon that side which lies in contact with the part over which they play, where they present a free articular facet. They may be divided into two kinds—those which glide over the articular surfaces of the joints, and those which play over the cartilaginous facets found on the surfaces of certain bones.

The sesamoid bones of the joints in the upper extremity are two on the palmar surface of the metacarpophalangeal joint in the thumb, developed in the tendons of the *Flexor brevis pollicis*; one on the palmar surface of the interphalangeal joint of the thumb; occasionally one or two opposite the metacarpophalangeal articulations of the fore and little fingers; and, still more rarely, one opposite the same joints of the third and fourth fingers. In the lower extremity, the patella, which is developed in the tendon of the *Quadriceps extensor*; two small sesamoid bones, found in the tendons of the *Flexor brevis hallucis*, opposite the metatarsophalangeal joint of the great toe; one sometimes over the interphalangeal joint of the great toe; and occasionally one in the metatarsophalangeal joint of the second toe, the little toe, and, still more rarely, the third and fourth toes.

Those found in the tendons which glide over certain bones occupy the following situations: One sometimes found in the tendon of the *Biceps brachii*, opposite the tuberosity of the radius; one in the tendon of the *Peroneus longus*, where it glides through the groove in the cuboid bone; one appears late in life in the tendon of the *Tibialis anticus*, opposite the smooth facet of the internal cuneiform bone; one is found in the tendon of the *Tibialis posticus*, opposite the inner side of the head of the astragalus; one in the outer head of the *Gastrocnemius*, behind the outer condyle of the femur; and one in the conjoined tendon of the *Psoas* and *Iliacus*, where it glides over the os pubis. Sesamoid bones are found occasionally in the tendon of the *Gluteus maximus*, as it passes over the great trochanter, and in the tendons which wind around the inner and outer malleoli.

THE ARTICULATIONS, OR JOINTS.

THE various bones of which the skeleton consists are connected at different parts of their surfaces, and such connections are designated by the name of **joints**, or **articulations**. Certain joints are *immovable*, as those between the cranial bones (with the exception of the mandible). In an immovable joint the adjacent margins of the bones are applied in close contact, a thin layer of fibrous membrane, the **sutural ligament**, or, as at the base of the skull, in certain situations, a thin layer of cartilage, being interposed. Where slight movement is required, combined with great strength, the osseous surfaces are united by tough and elastic **fibrocartilages**, as in the joints between the vertebral bodies and in the interpubic articulation; but in the *movable* joints the bones forming the articulation are generally expanded for greater convenience of mutual connection, covered by hyaline **cartilage**, held together by strong bands or *capsules* of fibrous tissue called **ligaments**, and partially lined by a membrane, the **synovial membrane**, which transudes a fluid to lubricate the various parts of which the joint is formed; so that the structures which enter into the formation of a joint are bone, hyaline cartilage, fibrocartilage, ligament, and synovial membrane.

Bone.—Bone constitutes the fundamental element of all the joints. In the long bones the extremities are the parts which form the articulations; they are generally somewhat enlarged, and consist of spongy, cancellous tissue, with a thin coating of compact substance. The layer of compact bone which forms the articular surface, and to which the cartilage is attached, is called the **articular lamella**. It is of a white color, extremely dense, and varies in thickness. Its structure differs from ordinary bone tissue in this respect, that it contains no Haversian canals, and its lacunæ are much larger than in ordinary bone and have no canaliculi. The vessels of the cancellous tissue, as they approach the articular lamella, turn back in loops, and do not perforate it; this layer is consequently more dense and firmer than ordinary bone, and is evidently designed to form a firm and unyielding support for the articular cartilage. In the flat bones the articulations usually take place at the edges, and, in the short bones, at various parts of their surface.

Cartilage.—There are three varieties of cartilage—*A*, hyaline; *B*, fibrocartilage; and *C*, yellow elastic cartilage; of these, but two, hyaline and fibrocartilage are utilized in the structure of a joint.

In general, cartilage consists of a genetic investing membrane, the **perichondrium**, surrounding the cartilage **substance proper**. The latter consists of the **cellular elements**, or **chondroblasts**, and the **intercellular substance**, or **matrix**.

The **perichondrium** is composed chiefly of white fibrous connective tissue with a few added yellow elastic fibres and cellular elements. The *outer* part contains few cells, and is called the *fibrous layer*. The *inner* part, or *genetic layer*, contains the bloodvessels, and is rich in flattened, elongated, or spindle-shaped cells, the chondroblasts.

The **chondroblasts** vary in shape; those immediately beneath the perichondrium are flat and elongated, while those farther in become larger and oval in form. Each cell contains a prominent nucleus embedded in a clear protoplasm that may contain one or more vacuoles. Each cell is sharply outlined, and lies in a space called the **lacuna**, but two or more cells may be seen to occupy the same lacuna. The matrix immediately surrounding the lacuna is somewhat differentiated from the remaining matrix, and is called the **capsule** of the lacuna.

The **matrix** varies in the different varieties of cartilage. In hyaline cartilage it is bluish or pearly in appearance, and under low magnification is apparently homogeneous; in the fibrocartilage the matrix consists mainly of white fibrous tissue arranged in bundles of varying size with islands of hyaline matrix and cartilage cells at intervals; the matrix of elastic cartilage is mainly yellow elastic tissue with islands of hyaline matrix and cartilage cells.

A. Hyaline cartilage is surrounded by its perichondrium, internal to which is found the apparently homogeneous or slightly granular matrix. If the latter be examined by polarized light or be first treated with potassium hydrate, the fundamental fibrillæ are discernible. The fibrils form a meshwork that contains the hyaline substance and cells.

In joints the hyaline cartilage is found as a thin layer covering the articular surfaces of the bones concerned, and is here called **articular cartilage**. In this form the peripheral cells are parallel to the surface; deeper in toward the bone the cells become arranged in rows at right angles to the surface. The latter condition may account for the vertical splitting of articular cartilage that occurs in certain diseases.

Hyaline cartilage is also found in the **costal, tracheal, bronchial**, and most of the **laryngeal cartilages**. It tends to calcify and even ossify in old age, and upon boiling yields a substance called *chondrin*.

The hyaline cartilage that covers the joint surfaces of the bones, by its elasticity enables it to break the force of any concussion, while its smoothness affords ease and freedom of movement. It varies in thickness according to the shape of the articular surface on which it lies; where this is convex the cartilage is thickest at the centre, where the greatest pressure is received; the reverse is the case on the concave articular surfaces.

FIG. 213.—Sections of cartilage. **A.** Hyaline cartilage. *a.* Fibrous layer of perichondrium. *b.* Genetic layer of perichondrium. *c.* Youngest chondroblasts. *d.* Older chondroblasts. *e.* Capsule. *f.* cells. *g.* Lacuna. **B.** Elastic cartilage. **C.** White fibrocartilage. (Radasch.)

B. Fibrocartilage is surrounded by a perichondrium; its **matrix** differs from that of the hyaline variety in consisting chiefly of white fibrous tissue arranged in bundles with little islands of hyaline substance and cells scattered here and there. It is found in the intra-articular cartilages, deepening joint cavities, and in the intervertebral disks. It is arranged in three groups—(1) intra-articular, (2) connecting, and (3) circumferential.

1. The **articular fibrocartilages**, or **articular disks** (*menisci articulares*), are flattened, fibrocartilaginous plates, of a round, oval, triangular, or sickle-like form, interposed between the articular cartilages of certain joints. They are free on both surfaces, thinner toward their centre than at their circumference, and held in position by the attachment of their margins and extremities to the surrounding ligaments. The synovial membrane of the joint is prolonged over them a short distance from their attached margins. They are found in the temporomandibular, sternoclavicular, acromioclavicular, wrist- and knee-joints. These cartilages are

usually found in those joints which are most exposed to violent concussion and subject to frequent movements. Their use is to maintain the apposition of the opposed surfaces in their various motions; to increase the depth of the articular surfaces and give ease to the gliding movement; to moderate the effects of great pressure and deaden the intensity of the shocks to which the parts may be subjected. Humphry has pointed out that these intra-articular fibrocartilages serve an important purpose in increasing the variety of movements in a joint. Thus, in the knee-joint there are two kinds of motion—viz., angular movement and rotation—although it is a hinge-joint, in which, as a rule, only one variety of motion is permitted; the former movement takes place between the condyles of the femur and the articular cartilages, the latter between the cartilages and the head of the tibia. So, also, in the temporomandibular joint, the upward and downward movement of opening and shutting the mouth takes place between the fibrocartilage and the mandible, the grinding movement between the glenoid cavity and the fibrocartilage, the latter moving with the mandible.

Intra-articular cartilages may divide the joint into two distinct cavities, as in the temporomandibular articulation. The periphery of an articular cartilage is attached particularly to the capsule, and may also be attached to the nonarticular portion of the bone. The semilunar cartilages of the knee resemble tendon more than they do cartilage. The fibres are arranged in dense, more or less parallel bundles, separated by small, scattered hyaline cells, and the disks are attached to the bone by thin layers of hyaline cartilage.

2. The **connecting fibrocartilages** are interposed between the bony surfaces of those joints which admit of only slight mobility, as between the bodies of the vertebræ and between the pubic bones. They form disks which adhere closely to both of the opposed surfaces, and are composed of concentric rings of fibrous tissue, with cartilaginous laminae interposed, the former tissue predominating toward the circumference, the latter toward the centre.

3. The **circumferential fibrocartilages** consist of a rim of fibrocartilage, which surrounds the margin of some of the articular cavities, as the cotyloid cavity of the hip and the glenoid cavity of the shoulder; they serve to deepen the articular surface, and to protect its edges.

Elastic cartilage, although not utilized in joints, may be considered here. It is surrounded by a perichondrium, and its matrix differs from the preceding varieties in being composed chiefly of yellow elastic tissue. It is found in the pinna of the ear, Eustachian tube, epiglottis, and small cartilages of the larynx. It does not ossify or calcify.

Cartilage, in the adult, is an avascular tissue, and although vessels at times are seen in the costal cartilages, they do not nourish it, as no branches are given off. Nerves are likewise absent.

Ligaments consist of bands of various forms, serving to connect the articular extremities of bones, and are composed mainly of coarse bundles of very dense, white, fibrous tissue placed parallel with, or closely interlaced with, one another, and presenting a white, shining, silvery aspect. A ligament is pliant and flexible, so as to allow of the most perfect freedom of movement, but it is strong, tough, and inextensible, so as not readily to yield under the most severely applied force; it is consequently well adapted to serve as the connecting medium between the bones. Some ligaments consist entirely of **yellow elastic tissue**, as the ligamenta subflava, which connect together the adjacent arches of the vertebræ in man, and the ligamentum nuchae in the lower animals are composed of yellow elastic tissue. In these cases it will be observed that the elasticity of the ligament is intended to act as a substitute for muscular power.

Synovial membrane is a thin, delicate, serous membrane, arranged in its simplest form like a short, wide tube, attached by its open ends to the margins of the articular cartilages and covering the inner surfaces of the various ligaments which connect the articulating surfaces, so that, along with cartilages, it completely encloses the joint-cavity. Its transudate is thick, viscid, and glairy, like the white of an egg, hence it is termed **synovia**. It is composed of a single layer of endothelial cells resting upon a thin layer of fibroelastic (subendothelial) tissue. The synovial membranes found in the body admit of subdivision into three kinds—articular, bursal, and vaginal.

Articular synovial membrane is found in every freely movable joint. It lines the capsule of the joint and is reflected upon the nonarticular intracapsular portion of the bones which enter into the formation of the joint. In the fetus this membrane is said, by Toynebee, to

be continued over the surface of the cartilages; but in the adult it merely encroaches for a short distance upon the margins of the cartilages, to which it is firmly attached; it then invests the inner surface of the capsular or other ligaments enclosing the joint, and is reflected over the surface of any tendons passing through its cavity, as the tendons of the Popliteus in the knee and the tendon of the Biceps in the shoulder. In some of the joints the synovial membrane is thrown into folds, which pass across the cavity. They are called **synovial ligaments**, and are especially distinct in the knee. These folds, when large, frequently contain considerable quantities of fat, which acts as a cushion between the two articular surfaces and serves a valuable purpose in filling up gaps. In some joints there are flattened folds, subdivided at their margins into fringe-like processes (**synovial villi**), the vessels of which have a convoluted arrangement. These latter generally project from the synovial membrane near the margin of the cartilage and lie flat upon its surface. They consist of fibroelastic tissue covered with endothelium, and contain fat-cells in variable quantities, and, more rarely, isolated cartilage-cells. Under certain diseased conditions similar processes are found covering the entire surface of the synovial membrane, forming a mass of pedunculated fibrofatty growths which project into the joint. Similar structures are also found in some of the bursal and vaginal synovial membranes.

The **bursal synovial membranes** are sacs interposed between surfaces which move upon each other, producing friction, as in the gliding of a tendon or of the integument over projecting bony surfaces. There are two groups of synovial bursæ designated according to situation: (1) **Subcutaneous synovial bursæ** (*bursæ mucosæ subcutaneæ*) (Fig. 214) are those situated between the integument and a prominent process of bone. Subcutaneous bursæ are found between the integument and the front of the patella, over the olecranon, the malleoli, and other prominent parts. (2) **Subtendinous synovial bursæ** (*bursæ mucosæ subtendineæ*) (Fig. 214) are those situated between tendons or muscles and the bony or cartilaginous surfaces over which the tendons or muscles glide. For example, a bursa is placed between the Glutei muscles and the surface

FIG. 214.—Scheme of a serous bursa. (Poirier and Charpy.)

of the great trochanter. Subtendinous bursæ are found often about joints and not unusually communicate directly with the cavity of the joint by means of an opening in the joint capsule, the synovial membrane of the joint being continuous with the synovial membrane of the bursa. For instance, the bursa between the tendon of the Psoas and Iliacus muscles and the capsular ligament of the hip communicates with the hip-joint; and the bursa between the under surface of the Subscapularis muscle and the neck of the scapula communicates with the shoulder-joint. Bursæ consist of a thin wall of connective tissue, lined by endothelial cells, and contain a viscid fluid.

The **vaginal synovial membrane** (Figs. 257 and 365), which is the **synovial sheath** or the **thecal synovial bursa** (*vagina mucosa tendinis*), serves to facilitate the gliding of a tendon in the osseofibrous canal through which it passes. The membrane is here arranged in the form of a sheath, one layer of which adheres to the wall of the canal, and the other is reflected upon the surface of the contained tendon, the space between the two surfaces of the membrane containing synovia. These sheaths are chiefly found surrounding the tendons of the Flexor and Extensor muscles of the fingers and toes as they pass through the osseofibrous canals in the hand or foot. A vaginal sheath covers the long head of the Biceps brachii muscle from its origin to the surgical neck of the humerus (Fig. 247).

Subjacent to the synovial membrane of certain joints are found pads of adipose tissue, the **synovial pads**. These serve to fill up large spaces, and by adapting themselves to changes of position maintain the form of the joint during movement.

The **articulations** are divided into three classes—**synarthrosis**, or immovable; **amphiarthrosis**, or mixed; and **diarthrosis**, or movable joints.

Synarthrosis (Immovable Articulation).—Synarthrosis includes all those articulations in which the surfaces of the bones are in almost direct contact, being fastened together by an intervening mass of connective tissue, and in which there

FIG. 215.—Section across the sagittal suture.

FIG. 216.—Section through the occipitospinous synchondrosis of an infant.

is no joint cavity and no appreciable motion. Examples of synarthrosis are the joints between the bones of the cranium and of the face, excepting those of the mandible. The varieties of synarthrosis are four in number—sutura, schindylesis, gomphosis, and synchondrosis.

FIG. 217.—Diagrammatic section of a symphysis.

The **sutura** is that form of articulation met with only in the skull, where the contiguous margins of flat bones are apparently but not really in immediate contact, a thin layer of fibrous tissue, **sutural membrane**, being interposed. This membrane is continuous externally with the pericranium and internally with the

FIG. 218.—Diagrammatic section of a diarthrodial joint.

FIG. 219.—Diagrammatic section of a diarthrodial joint, with an intra-articular fibrocartilage.

dura. In some of the sutures the sutural membrane gradually disappears as age advances and the two bones form an osseous fusion. Where the articulating surfaces are connected by a series of processes and indentations interlocked,

it is termed a **true suture**, or *sutura vera*, of which there are three varieties—*sutura dentata*, *serrata*, and *limbosa*. The *sutura dentata* is so called from the tooth-like form of the projecting articular processes, as in the suture between the parietal bones. In the *sutura serrata* the edges of the two bones forming the articulation are serrated like the teeth of a fine saw, as between the two portions of the frontal bone. In the *sutura limbosa* besides the dentated processes, there is a certain degree of bevelling of the articular surfaces, so that the bones overlap each other, as in the suture between the parietal and frontal bones. When the articulation is formed by roughened surfaces placed in apposition with one another, it is termed the **false suture**, of which there are two kinds—the *sutura squamosa*, formed by the overlapping of two contiguous bones by broad bevelled margins, as in the squamoparietal (squamous) suture; and the *sutura harmonia*, where there is simple apposition of two contiguous, rough, bony surfaces, as in the articulation between the two maxillæ or of the horizontal plates of the palate bones.

Schindylesis is that form of articulation in which a thin plate of bone is received into a cleft or fissure formed by the separation of two laminæ in another bone, as in the articulation of the rostrum of the sphenoid and perpendicular plate of the ethmoid with the vomer, or in the reception of the latter in the fissure between the maxillæ and palate bones.

A **gomphosis** is an articulation formed by the insertion of a conical process into a socket, as a nail is driven into a board; this is not illustrated by any articulation between bones, properly so called, but is seen in the articulation of the teeth with the alveoli of the maxillæ and mandible.

A **synchondrosis** is a joint in which the connecting medium is hyaline cartilage. This is a temporary form of joint, because the hyaline cartilage becomes converted into bone before adult life. Such joints are found between the epiphyses and shafts of long bones, between the occipital and the sphenoid at, and for some years after, birth, and between the petrous portion of the temporal and the jugular process of the occipital.

Amphiarthrosis (Mixed Articulation).—In the amphiarthrosis there is only a slight amount of motion. Two varieties of this form of joint are recognized: A **symphysis** is that joint in which the contiguous osseous surfaces are connected by a broad flattened disk of fibrocartilage which is attached to both bases as in the articulation between the bodies of two vertebræ and between the two pubic bones. A partial joint cavity and an incomplete synovial membrane may be found in such joints.

A **syndesmosis** is an amphiarthrodial joint in which the bony surfaces are joined by an interosseous ligament, as in the inferior tibiofibular articulation.

Diarthrosis (Movable Articulation).—This form of articulation includes the greater number of the joints in the body, mobility being their distinguishing character. They are formed by the approximation of two contiguous bony surfaces covered with cartilage, connected by ligaments and lined with synovial membrane. The varieties of joints in this class have been determined by the kind of motion permitted in each. There are two varieties in which the movement is uniaxial; that is to say, all movements take place around one axis. In one form, the **ginglymus**, or **hinge-joint**, this axis is, practically speaking, transverse; in the other, the **trochoid**, or **pivot-joint**, it is longitudinal. There are two varieties where the movement is **biaxial** or around two horizontal axes at right angles to each other or at any intervening axis between the two. These are the **condyloid joint** and the **saddle-joint**. There is one form of joint where the movement is **polyaxial**, the **enarthrosis**, or **ball-and-socket joint**. And finally there are the **arthrodia**, or **gliding joints**. In a diarthrosis there is always a joint cavity lined with synovial membrane—the articular surfaces of the bones are covered with hyaline cartilage, and the bones are held in contact by ligaments.

The **ginglymus**, or **hinge-joint**, is that form of joint in which the articular surfaces are moulded to each other in such a manner as to permit motion only in one plane, forward and backward; the extent of motion at the same time being considerable. The direction which the distal bone takes in this motion is never in the same plane as that of the axis of the proximal bone, and there is always a certain amount of alteration from the straight line during flexion. The articular surfaces are connected together by strong lateral ligaments, which form their chief bond of union. The most perfect forms of ginglymus are the interphalangeal joints, and the joint between the humerus and the ulna; the knee and ankle-joints are less perfect, as they allow a slight degree of rotation or lateral movement in certain positions of the limb.

A **trochoid**, or **pivot-joint** or **rotary joint**, is one in which the movement is limited to rotation; the joint is formed by a pivot-like process turning within a ring, or the ring on the pivot, the ring being formed partly of bone, partly of ligament. In the superior radioulnar articulation the ring is formed partly by the lesser sigmoid cavity of the ulna and in the rest of its extent by the orbicular ligament; here the head of the radius rotates within the ring. In the articulation of the odontoid process of the axis with the atlas the ring is formed in front by the anterior arch of the atlas; behind, by the transverse ligament; here the ring rotates around the odontoid process.

Condylloid or **biaxial articulation** is that form of joint in which an ovoid articular head, or condyle, is received into an elliptical cavity in such a manner as to permit of flexion and extension, adduction and abduction and circumduction, but no axial rotation. The articular surfaces are connected together by anterior, posterior, and lateral ligaments. An example of this form of joint is found in the wrist.

Articulation by reciprocal reception, or **saddle-joint**, is that variety in which the articular surfaces are concavo-convex; that is to say, they are inversely convex in one direction and concave in the other. The movements are the same as in the preceding form; that is to say, there is flexion, extension, adduction, abduction, and circumduction, but no axial rotation. The articular surfaces are connected by a capsular ligament. The best example of this form of joint is the carpometacarpal joint of the thumb.

An **enarthrosis**, or **ball-and-socket joint**, is that form of joint in which the distal bone is capable of motion around an indefinite number of axes which have one common centre. It is formed by the reception of a globular head into a deep cup-like cavity, the parts being kept in apposition by a capsular ligament strengthened by accessory ligamentous bands. Examples of this form of articulation are found in the hip- and shoulder-joints.

Arthrodia.—Arthrodia is that form of joint which admits of a gliding movement; it is formed by the approximation of plane surfaces or of one slightly concave to one slightly convex, the amount of motion between them being limited by the ligaments, or osseous processes, surrounding the articulation; as in the articular processes of the vertebræ, the carpal joints, except that of the os magnum with the scaphoid and semilunar bones, and the tarsal joints with the exception of the joint between the astragalus and the scaphoid.

Below, in tabular form, are the names, distinctive characters, and examples of the different kinds of articulations.

Synarthrosis, or Im-movable Joint. Sur-faces separated by fibrous membrane or by a line of cartilage, without any interven-ing synovial cavity, and immovably con-nected with e a c h other.

As in joints of cran-ium and face (except mandible).

Amphiarthrosis, Mixed Articulation.

Diarthrosis, Movable Joint.

Sutura. Artic-ulation by processes and indentations interlocked.

Sutura vera (true) articulate by indent-ed borders.

Sutura notha (false), articulate by rough surfaces.

Dentata, having tooth-like processes.

As in interparietal suture.

Serrata, having serrated edges like the teeth of a saw.

As in interfrontal suture.

Limbose, having bevelled margins and dentated pro-cesses.

As in frontoparietal su-ture.

Squamosa, formed by thin bevelled margins, over-lapping each other.

As in squamoparietal suture.

Harmonia, formed by the apposition of contigu-ous rough surfaces.

As in intermaxillary su-ture.

Schindylesis.—Articulation formed by the reception of a thin plate of one bone into a fissure of another.

As in articulation of rostrum of sphenoid with vomer.

Gomphosis.—Articulation formed by the insertion of a conical process into a socket—the teeth.

Symphysis.—Surfaces connected by fibrocartilage. There is a partial joint cavity and may be an incomplete synovial membrane. Has limited motion. As in joints between bodies of vertebræ.

Syndesmosis.—Surfaces united by an interosseous ligament. As in the inferior tibiofibular articulation.

Ginglymus.—Hinge-joint; motion limited to two directions, forward and backward. Articular surfaces fitted together so as to permit of movement in one plane. As in the interphalangeal joints and the joint between the humerus and the ulna.

Trochoid, or Pivot-joint.—Articulation by a pivot process turning within a ring or ring around a pivot. As in superior radioulnar articulation and atlanto-axial joint.

Condylod.—Ovoid head received into elliptical cavity. Movements in every direction except axial rotation. As the wrist-joint.

Reciprocal Reception (saddle-joint).—Articular surfaces inversely con-vex in one direction and concave in the other. Movement in every direction except axial rotation. As in the carpometacarpal joint of the thumb.

Enarthrosis.—Ball-and-socket joint; capable of motion in all directions. Articulations by a globular head received into a cup-like cavity. As in hip- and shoulder-joints.

Arthrodia.—Gliding joint; articulations by plane surfaces, which glide upon each other. As in carpal and tarsal articulations.

The Kinds of Movement Admitted in Joints.

The movements admissible in the joints may be divided into four kinds—gliding, angular movement, circumduction, and rotation. These movements are often, however, more or less combined in the various joints, so as to produce an infinite variety, and it is seldom that we find only one kind of motion in any particular joint.

Gliding movement is the most simple kind of motion that can take place in a joint, one surface gliding or moving over another without any angular or rotatory movement. It is common to all movable joints, but in some, as in the articu-lations of the carpus and tarsus, it is the only motion permitted. This movement

is not confined to plane surfaces, but may exist between any two contiguous surfaces, of whatever form, limited by the ligaments which enclose the articulation. Gliding over a wide range, as is seen in the sliding of the patella over the condyles of the femur, is called **coaptation**.

Angular movement occurs only between the long bones, and by it the angle between the two bones is increased or diminished. It may take place in four directions—forward and backward, constituting **flexion** or **bending** and **extension** or **straightening**, or inward toward and outward from the medial line of the body, constituting **adduction** and **abduction**. Abduction of a limb is movement away from the medial line of the body. Adduction of a limb is movement toward the medial line of the body. In the fingers and toes the significance of the terms are different; abduction means movement of the fingers away from the middle finger or of the toe away from the second toe; adduction means movement of fingers toward the middle finger or of the toes toward the second toe. The strictly ginglymoid or hinge-joints admit of flexion and extension only. Abduction and adduction, combined with flexion and extension, are met with in the more movable joints; as in the hip-, shoulder-, and metacarpal-joint of the thumb, and partially in the wrist. When two anterior surfaces are brought nearer together, as by bending the elbow or wrist, we speak of the movement as **anterior** or **ventral flexion**. Ventral flexion of the wrist is also called **volar** or **palmar flexion**. If two posterior surfaces are brought nearer together, as by bending the knee or extending the wrist, we speak of the movement as **posterior** or **dorsal flexion**.

At the wrist-joint the bending of the ulnar margin of the hand toward the ulnar side of the forearm is **ulnar flexion**; the bending of the radial margin of the hand toward the radial side of the forearm is **radial flexion**.

Circumduction is that limited degree of motion which takes place between the head of the bone and its articular cavity, while the extremity and sides of the limb are made to circumscribe a conical space, the base of which corresponds with the inferior extremity of the limb, the apex with the articular cavity; this kind of motion is best seen in the shoulder- and hip-joints.

Rotation is the movement of a bone upon an axis, which is the axis of the pivot on which the bone turns, as in the articulation between the atlas and axis, when the odontoid process serves as a pivot around which the atlas turns; or else is the axis of a pivot-like process which turns within a ring, as in the rotation of the radius upon the humerus.

Ligamentous Action of Muscles.—The movements of the different joints of a limb are combined by means of the long muscles which pass over more than one joint, and which, when relaxed and stretched to their greatest extent, act as elastic ligaments in restraining certain movements of one joint, except when combined with corresponding movements of the other, these latter movements being usually in the opposite direction. Thus, the shortness of the Hamstring muscles prevents complete flexion of the hip, unless the knee-joint is also flexed, so as to bring their attachments nearer together. The uses of this arrangement are threefold: (1) It coordinates the kinds of movement which are the most habitual and necessary, and enables them to be performed with the least expenditure of power. "Thus, in the usual gesture of the arms, whether in grasping or rejecting, the shoulder and the elbow are flexed simultaneously, and simultaneously extended," in consequence of the passage of the Biceps and Triceps brachii over both joints. (2) It enables the short muscles which pass over only one joint to act upon more than one. "Thus, if the Rectus femoris remain tonically of such length that, when stretched over the extended hip, it compels extension of the knee, then the Gluteus maximus becomes not only an extensor of the hip, but an extensor of the knee as well." (3) It provides the joints with ligaments which, while they are of very great power in resisting movements to an extent incompatible with the mechanism of the joint, at the same time spontaneously yield when necessary. "Taxed beyond its strength, a ligament will be ruptured, whereas a contracted muscle is easily relaxed; also, if neighboring joints be united by ligaments, the amount of flexion or extension of each must remain in constant proportion to that of the other; while, if the union be by muscles, the separation of the points of attachment of those muscles may vary considerably in different varieties of move-

ment, the muscles adapting themselves tonically to the length required."¹ Dr. W. W. Keen points out how important it is "that the surgeon should remember this ligamentous action of muscles in making passive motion—for instance, at the wrist after Colles' fracture. If the fingers be extended, the wrist can be flexed to a right angle. If, however, they be first flexed, as in 'making a fist,' flexion at the wrist is strictly limited to from 40 to 50 degrees in different persons, and is very painful beyond that point. Hence, passive motion here should be made with the fingers extended. In the leg, when flexing the hip, the knee should be flexed." Dr. Keen further points out that "a beautiful illustration of this is seen in the perching of birds, whose toes are forced to clasp the perch by just such a passive ligamentous action so soon as they stoop. Hence, they can go to sleep and not fall off the perch."

The articulations may be arranged into those of the trunk, those of the upper extremity, and those of the lower extremity.

ARTICULATIONS OF THE TRUNK.

These may be divided into the following groups, viz.:

I. Articulations of the Vertebral Column.

The different segments of the vertebral column are connected by **spinal ligaments** (*ligamenta columnae vertebralis*), which may be divided into five sets: (1) Those connecting the **bodies** of the vertebrae (*intercentral*). (2) Those connecting the **laminae**. (3) Those connecting the **articular processes**. (4) Those connecting the **spinous processes**. (5) Those of the **transverse processes** (the last four kinds being known as *interneural*).

The articulations of the bodies of the vertebrae with each other form a series of amphiarthrodial joints; those between the articular processes form a series of arthrodial joints.

1. LIGAMENTS OF THE VERTEBRAL BODIES OR CENTRA (INTERCENTRAL LIGAMENTS).

Anterior Common Ligament.
Posterior Common Ligament.
Intervertebral Substance.

The **anterior common ligament** (*ligamentum longitudinale anterius*) (Figs. 222, 224, and 228) is a broad and strong band of longitudinal fibres which extends along the anterior (*ventral*) surface of the bodies of the vertebrae from the axis to the sacrum. It is broader below than above, thicker in the thoracic than in the cervical or lumbar regions, and somewhat thicker opposite the front of the body of each vertebra than opposite the intervertebral substance. It is attached,

¹ Dr. Cleland, in *Journal of Anatomy and Physiology*, 1866, No. 1, p. 85.

above, to the body of the axis by a pointed process, where it is continuous with the anterior atlanto-axial ligament, is connected with the tendon of insertion of the Longus colli muscle, and extends down as far as the upper bone of the sacrum. It consists of dense longitudinal fibres, which are intimately adherent to the intervertebral substance and the prominent margins of the vertebræ, but less closely to the middle of the bodies. In the latter situation the fibres are exceedingly thick, and serve to fill up the concavities on their front surface and to make the anterior surface of the vertebral column more even. This ligament is composed of several layers of fibres, which vary in length, but are closely interlaced with each other. The most superficial or longest fibres extend between four or five vertebræ. A second subjacent set extends between two or three vertebræ, while a third set, the shortest and deepest, extends from one vertebra to the next. At the side of the bodies the ligament consists of a few short fibres, which pass from one vertebra to the next, separated from the median portion by large oval apertures for the passage of vessels.

The **posterior common ligament** (*ligamentum longitudinale posterius*) (Figs. 227 and 228) is situated within the vertebral canal, and extends along the posterior (*dorsal*) surface of the bodies of the vertebræ from the body of the axis above, where

FIG. 220.—Vertebral bodies with ligaments, from behind. (Spalteholz.)

FIG. 221.—Intervertebral disk, with the adjacent vertebral bodies, from in front. (Spalteholz.)

it is continuous with the posterior occipito-axial ligament, to the sacrum below. It is broader above than below, and thicker in the thoracic than in the cervical or lumbar regions. In the situation of the intervertebral substance and contiguous margins

of the vertebræ, where the ligament is more intimately adherent, it is broad, and presents a series of dentations with intervening concave margins; but it is narrow and thick over the centre of the bodies, from which it is separated by the *venæ basis vertebræ*. This ligament is composed of smooth, shining, longitudinal fibres, denser and more compact than those of the anterior ligament, and formed of a superficial layer occupying the interval between three or four vertebræ, and of a deeper layer which extends between one vertebra and the next adjacent to it. It is separated from the *dura* of the spinal cord by some loose connective tissue, which is very liable to serous infiltration.

The **Intervertebral Fibrocartilages** (*fibrocartilagines intervertebrales*) (Figs. 221 and 222).—Each fibrocartilaginous disk is of lenticular form and of composite

structure. The disks are interposed between the adjacent surfaces of the bodies of the vertebræ from the axis to the sacrum, and form the chief bonds of connection between those bones. In young children intervertebral substance exists in the coccyx. These disks vary in shape, size, and thickness in different parts of the vertebral column. In shape they accurately correspond with the surfaces of the bodies between which they are placed, being oval in the cervical and lumbar regions, and circular in the thoracic. Their size is greatest in the lumbar region. In thickness they vary not only in the different regions of the vertebral column, but in different parts of the same disk; thus, they are thicker in front than behind in the cervical and lumbar regions, while they are uniformly thick in the thoracic region. The intervertebral disks form about one-fourth of the vertebral column, exclusive of the first two vertebræ; they are not equally distributed, however, between the various bones; the thoracic portion of the vertebral column having, in proportion to its length, a much smaller quantity than in the cervical and lumbar

FIG. 222.—Median section of a piece of the lumbar vertebral column, right half of section viewed from the left. (Spalteholz.)

regions, which necessarily gives to the latter parts greater pliancy and freedom of movement. The intervertebral disks are adherent, by their surfaces, to a thin layer of hyaline cartilage which covers the upper and under surfaces of the bodies of the vertebræ, and in which, in early life, the epiphyseal plates develop, and by their circumference are closely connected in front to the anterior, and behind to the posterior common ligament; while in the thoracic region they are connected laterally, by means of the interarticular ligament, to the heads of those ribs which articulate with two vertebræ; they, consequently, form part of the articular cavities in which the heads of these bones are received.

Structure of the Intervertebral Substance.—The outer portion of the intervertebral substance is composed of many layers of fibrous connective tissue. This enveloping portion is called the **annulus fibrosus**. The central portion of the disk is composed of soft, pulpy, highly elastic fibrocartilage, containing some bands of connective tissue. It is called the **nucleus pulposus**, is of a yellowish color, and rises up considerably above the surrounding level when the disk is divided horizontally. This pulpy substance, which is especially well developed in the lumbar region, is the remains of the notochord, and, according to Luschka, contains a small synovial cavity in its

centre. The outer layers of the disk are arranged concentrically one within the other, the outermost consisting of ordinary fibrous tissue, but the others and more numerous consisting of white fibrocartilage. These plates are not quite vertical in their direction, those near the circumference being curved outward and closely approximated; while those nearest the centre curve in the opposite direction, and are somewhat more widely separated. The fibres of which each plate is composed are directed, for the most part, obliquely from above downward, the fibres of adjacent plates passing in opposite directions and varying in every layer; so that the fibres of one layer are directed across those of another, like the limbs of the letter X. This laminar arrangement belongs to about the outer half of each disk. The pulpy substance presents no concentric arrangement, and consists of a fine fibrous matrix, containing angular cells, united to form a reticular structure. J. Bland Sutton¹ calls attention to the fact that in the human fetus a transverse ligamentous band crosses the dorsal aspect of the intervertebral disk and is continuous with the interosseous ligaments of the heads of the ribs; and also that a fetal ligamentous band exists in the ventral surface of the intervertebral disk which, after development, becomes the middle fasciculus of the stellate ligament. These bands are named by Sutton the **posterior conjugal ligaments** and the **anterior conjugal ligaments**.

Interneural articulations include the ligaments of the **laminæ**; **articular processes**, **spinous processes**, and **transverse processes**.

2. LIGAMENTS CONNECTING THE LAMINÆ.

Ligamenta Subflava.

The **ligamenta subflava** (*ligamenta intercruralia*) (Figs. 222 and 223) are interposed between the laminæ of the vertebræ, from the axis to the sacrum. They are most distinct when seen from the interior of the vertebral canal; when viewed from the outer surface they appear short, being overlapped by the laminæ. Each ligamentum subflavum consists of two lateral portions, which commence on each side at the root of either articular process, and pass backward to the point where the laminæ converge to form the spinous process, where their margins are in contact and to a certain extent united; slight intervals being left for the passage of small vessels. These ligaments consist of yellow elastic tissue, the fibres of which, almost perpendicular in direction, are attached to the anterior surface of the laminæ above, some distance from its inferior margin, and to the posterior surface, as well as to the margin of the lamina below. In the cervical region they are thin in texture, but very broad and long; they become thicker in the thoracic region, and in the lumbar acquire very considerable thickness. Their

FIG. 223.—Vertebral arches with ligamenta flava. (Spalteholz.)

¹ Ligaments: Their Nature and Morphology, 1887.

highly elastic property serves to preserve the upright posture and to assist in resuming it after the spine has been flexed. These ligaments do not exist between the occiput and atlas or between the atlas and axis.

3. LIGAMENTS CONNECTING THE ARTICULAR PROCESSES.

Capsular Ligaments.

The **capsular ligaments** (*capsulae articulares*) (Fig. 224) are thin and loose ligamentous sacs, attached to the contiguous margins of the articulating processes of each vertebra through the greater part of their circumference, and completed internally by the *ligamenta subflava*. They are longer and looser in the cervical than in the thoracic or lumbar regions. The capsular ligaments are lined on their inner surface with synovial membrane.

4. LIGAMENTS CONNECTING THE SPINOUS PROCESSES.

Supraspinous Ligament.

Ligamentum Nuchae.

Interspinous Ligaments.

The **supraspinous ligament** (*ligamentum supraspinale*) (Fig. 222) is a strong fibrous cord, which connects the apices of the spinous processes from the seventh cervical to the spinous processes of the sacrum. It is thicker and broader in the lumbar than in the thoracic region, and intimately blended, in both situations, with the neighboring aponeurosis. The most superficial fibres of this ligament connect three or four vertebræ; those deeper-seated pass between two or three vertebræ; while the deepest connect the contiguous extremities of neighboring vertebræ. It is continued upward to the external occipital protuberance as the *ligamentum nuchae*.

The **ligamentum nuchae** is a fibrous membrane which, in the neck, represents the supraspinous ligaments of the lower vertebræ. It extends from the external occipital protuberance and crest to the spinous process of the seventh cervical vertebra. From its anterior border a fibrous lamina is given off, which is attached to the posterior tubercle of the atlas, and to the spinous processes of all the cervical vertebræ, so as to form a septum between the muscles on either side of the neck. In man it is merely a rudiment of an important elastic band which, in some of the lower animals, serves to sustain the weight of the head.

The **interspinous ligaments** (*ligamenta interspinalia*) (Fig. 222), thin and membranous, are interposed between the spinous processes. Each ligament extends from the root to the summit of each spinous process and connects their adjacent margins. They meet the *ligamenta subflava* in front and the supraspinous ligament behind. They are narrow and elongated in the thoracic region; broader, quadrilateral in form, and thicker in the lumbar region; and only slightly developed in the neck.

5. LIGAMENTS CONNECTING THE TRANSVERSE PROCESSES.

Intertransverse Ligaments.

The **intertransverse ligaments** (*ligamenta intertransversaria*) (Fig. 235) consist of bundles of fibres interposed between the transverse processes. In the cervical region they consist of a few irregular, scattered fibres; in the thoracic, they are rounded cords intimately connected with the deep muscles of the back; in the lumbar region they are thin and membranous.

Movements of the Vertebral Column.—The movements permitted in the vertebral column are *flexion*, *extension*, *lateral movement*, *circumduction*, and *rotation*.

In *flexion* (*forward flexion*), or movement of the vertebral column forward, the anterior common ligament is relaxed, and the intervertebral substances are compressed in front, while the posterior common ligament, the ligamenta subflava, and the inter- and supraspinous ligaments are stretched, as well as the posterior fibres of the intervertebral disks. The interspaces between the laminae are widened, and the inferior articular processes of the vertebrae above glide upward upon the articular processes of the vertebrae below. Flexion is the most extensive of all the movements of the vertebral column.

In *extension* (*backward flexion*), or movement of the vertebral column backward, an exactly opposite disposition of the parts take place. This movement is not extensive, being limited by the anterior common ligament and by the approximation of the spinous processes.

Flexion and extension are greatest in the lower part of the lumbar region between the third and fourth and fourth and fifth lumbar vertebrae; above the third they are much diminished, and reach their minimum in the middle and upper part of the back. They increase again in the neck, the capability of motion backward from the upright position being in this region greater than that of the motion forward, whereas in the lumbar region the reverse is the case.

In *lateral flexion*, the sides of the intervertebral disks are compressed, the extent of motion being limited by the resistance offered by the surrounding ligaments and by the approximation of the transverse processes. This movement may take place in any part of the vertebral column, but has the greatest range in the neck and loins.

Circumduction is limited, and is produced merely by a succession of the preceding movements.

Rotation is produced by the twisting of the intervertebral substances; this, although only slight between any two vertebrae, produces a considerable extent of movement when it takes place in the whole length of the vertebral column, the front of the upper part of the column being turned to one or the other side. This movement takes place only to a slight extent in the neck, but is more pronounced in the upper part of the thoracic region, and is altogether absent in the lumbar region. It is thus seen that the *cervical region* enjoys the greatest extent of each variety of movement, flexion and extension, especially, being very extensive. In the *thoracic region* the three movements of flexion, extension, and circumduction are permitted only to a slight extent, while rotation is very extensive in the upper part and ceases below. In the lumbar region there is extensive flexion, extension, and lateral movement, but no rotation.

The movements permitted are mainly due to the shape and position of the articulating processes. In the loins the inferior articulating processes are turned outward and are embraced by the superior; this renders rotation in this region of the vertebral column impossible, while there is nothing to prevent a sliding upward and downward of the surfaces on each other, so as to allow of flexion and extension. In the thoracic region, on the other hand, the articulating processes, by their direction and mutual adaptation, especially at the upper part of the series, permit of rotation, but prevent extension and flexion, while in the cervical region the greater obliquity and lateral slant of the articular processes allow not only flexion and extension, but also rotation.

The principal muscles which produce *flexion* are the Sternomastoid, Rectus capitis anticus major, and Longus colli; the Scalenii; the abdominal muscles and the Psoas magnus. *Extension* is produced by the fourth layer of the muscles of the back, assisted in the neck by the Splenius, Semispinales dorsi et colli, and the Multifidus spinae. *Lateral* motion is produced by the fourth layer of the muscles of the back, by the Splenius and the Scalenii, the Quadratus lumborum and Psoas magnus, the muscles of one side only acting; and *rotation* by the action of the following muscles of one side only—viz., the Sternomastoid, the Rectus capitis anticus major, the Scalenii, the Multifidus spinae, the Complexus, and the abdominal muscles.

II. Articulation of the Atlas with the Axis (*Articulatio Atlantoepistrophica*).

The articulation of the atlas with the axis is of a complicated nature, comprising no fewer than four distinct joints. There is a pivot articulation between the odontoid process of the axis and the ring formed between the anterior arch of the atlas and the transverse ligament (Fig. 226). Here there are two joints—one in front between the posterior surface of the anterior arch of the atlas and the front of the odontoid process; the other between the anterior surface of the transverse ligament and the back of the process. Between the articular processes of the two bones there is a double arthrodial or gliding joint. The ligaments which connect these bones are the

Anterior Atlanto-axial.
Posterior Atlanto-axial.

Transverse.
Two Capsular.

The **anterior atlanto-axial ligament** (Figs. 224 and 228) is a strong, membranous layer, attached, *above*, to the lower border of the anterior arch of the atlas; *below*, to the base of the odontoid process and to the front of the body of the axis. It is strengthened in the middle line by a rounded cord, which is attached, *above*, to the tubercle on the anterior arch of the atlas, and *below* to the body of the axis, being a continuation upward of the anterior common ligament of the vertebral column. The ligament is in relation, in front, with the *Recti antici majores*.

The **posterior atlanto-axial ligament** (Figs. 225 and 228) is a broad and thin membranous layer, attached, *above*, to the lower border of the posterior arch of the atlas; *below*, to the upper edge of the laminae of the axis. This ligament supplies the place of the *ligamenta subflava*, and is in relation, behind, with the *Inferior oblique muscles*.

The **transverse ligament of the atlas**¹ (*ligamentum transversum atlantis*) (Figs. 227 and 228) is a thick, strong band, which arches across the ring of the atlas, and serves to retain the odontoid process in firm connection with its anterior

FIG. 224.—Occipital bone and first three cervical vertebrae with ligaments, from in front. (Spalteholz.)

arch. This ligament is flattened from before backward, broader and thicker in the middle than at either extremity, and firmly attached on each side to a small tubercle on the inner surface of the lateral mass of the atlas. As it crosses the odontoid process, a small fasciculus is derived from its upper, and another from its lower border; the former passing upward, to be inserted into the anterior surface of the foramen magnum of the occipital bone; the latter, downward, to be attached to the posterior surface of the body of the axis; hence, the whole ligament has received the name of **cruciform ligament** (*ligamentum cruciatum atlantis*). A synovial surface is interposed between the odontoid process and the transverse ligament, and one is placed between the anterior surface of the odontoid

¹ It has been found necessary to describe the transverse ligament with those of the atlas and axis; but the student must remember that it is really a portion of the mechanism by which the movements of the head on the vertebral column are regulated; so that the connections between the atlas and axis ought always to be studied together with those between the latter bones and the skull.

process and the anterior arch of the atlas. The transverse ligament divides the vertebral foramen of the atlas into two unequal compartments; of these, the posterior and larger serves for the transmission of the cord and its membranes and the spinal accessory nerves; the anterior and smaller contains the odontoid process. Since the space between the anterior arch of the atlas and the transverse ligament is smaller at the lower part than the upper (because the transverse ligament embraces tightly the narrow neck of the odontoid process), this process is retained in firm connection with the atlas after all the other ligaments have been divided.

The **capsular ligaments** (*capsulae articulares*) (Figs. 225 and 227) are two thin and loose capsules, connecting the lateral masses of the atlas with the superior articular surfaces of the axis, the fibres being strengthened at the posterior and inner part of each articulation by an **accessory ligament**, which is attached below to the body of the axis near the base of the odontoid process.

Synovial Membranes (Fig. 226).—There are *four* synovial membranes in this articulation—one lining the inner surface of each of the capsular ligaments; one between the anterior surface of the odontoid process and the anterior arch of the atlas, the **atlanto-odontoid joint**; and one between the posterior surface of the odontoid process and the transverse ligament, the **syndesmo-odontoid joint**. The latter often communicates with those between the condyles of the occipital bone and the articular surfaces of the atlas.

Movements.—This joint allows the rotation of the atlas (and, with it, of the cranium) upon the axis, the extent of rotation being limited by the odontoid ligaments.

The principal muscles by which this action is produced are the Sternomastoid and Complexus of one side, acting with the Rectus capitis anticus major, Splenius, Trachelomastoid, Rectus capitis posticus major, and Inferior oblique of the other side.

ARTICULATIONS OF THE VERTEBRAL COLUMN WITH THE CRANIUM.

The ligaments connecting the vertebral column with the cranium may be divided into two sets—those connecting the occipital bone with the atlas, and those connecting the occipital bone with the axis.

III. Articulation of the Atlas with the Occipital Bone (Articulatio Atlanto-occipitalis).

This articulation is a double condyloid joint. Its ligaments are the

Anterior Occipito-atlantal. Posterior Occipito-atlantal.
Two Capsular.

The **anterior occipito-atlantal ligament** (*membrana atlantooccipitalis anterior*) (Figs. 224 and 228) is a broad membranous layer, composed of densely woven fibres, which passes between the anterior margin of the foramen magnum above, and the whole length of the upper border of the anterior arch of the atlas below. Laterally, it is continuous with the capsular ligaments. In the middle line in front it is strengthened by a strong, narrow, rounded cord, which is attached, above, to the basilar process of the occiput, and, below, to the tubercle on the anterior arch of the atlas, and which is a continuation of the anterior common ligament. This ligament is in relation, in *front*, with the Recti antici minores; *behind*, with the odontoid ligaments.

The **posterior occipito-atlantal ligament** (*membrana atlantooccipitalis posterior, posterior occipito-atlantal ligament*) (Figs. 225 and 228) is a very broad but thin membranous lamina intimately blended with the dura. It is connected, *above*, to the posterior margin of the foramen magnum; *below*, to the upper border of the posterior arch of the atlas. This ligament is incomplete at each side, and

forms, with the superior intervertebral notch, an opening for the passage of the vertebral artery and suboccipital nerve. The fibrous band which arches over the artery and nerve sometimes becomes ossified. The ligaments are in relation, *behind*, with the Recti postici minores and Obliqui superiores; in *front*, with the dura of the vertebral canal, to which they are intimately adherent.

FIG. 225.—Occipital bone, first and second cervical vertebrae with ligaments from behind. (Spalteholz.)

The **capsular ligaments** (*capsulae articulares*) (Fig. 227) surround the condyles of the occipital bone, and connect them with the articular processes of the atlas; they consist of thin and loose capsules, which enclose the synovial membranes of the articulations.

Synovial Membranes.—There are *two* synovial membranes in this articulation, one lining the inner surface of each of the capsular ligaments. These occasionally communicate with that between the posterior surface of the odontoid process and the transverse ligament.

FIG. 226.—Articulation between odontoid process and atlas.

Movements.—The movements permitted in this joint are flexion and extension, which give rise to the ordinary forward and backward nodding of the head. Slight lateral motion to one or the other side may also take place. When either of these actions is carried beyond a slight extent, the whole of the cervical portion of the spine assists in its production. *Flexion* is mainly produced by the action of the Rectus capitis anticus major et minor and the Sternomastoid muscles; *extension* by the Rectus capitis posticus major et minor, the Obliquus superior, the

Complexus, Splenius, and upper fibres of the Trapezius. The Recti laterales are concerned in the lateral movement, assisted by the Trapezius, Splenius, Complexus, and the Sternomastoid of the same side, all acting together. According to Cruveilhier, there is a slight amount of rotation in this joint.

IV. Articulation of the Axis with the Occipital Bone.

The ligaments of this articulation are the

Occipito-axial.

Three Odontoid.

To expose these ligaments the vertebral canal should be laid open by removing the posterior arch of the atlas, the laminae and spinous process of the axis, and the portion of the occipital bone behind the foramen magnum, as seen in Fig. 227.

FIG. 227.—Occipito-axial and atlanto-axial ligaments. Posterior view, obtained by removing the arches of the vertebrae and the posterior part of the skull.

The **posterior occipito-axial ligament** (*membrana tectoria*) (Figs. 227 and 228) is situated within the vertebral canal. It is a broad, strong band, which covers the odontoid process and its ligaments, and appears to be a prolongation upward of, or a membrane due to fusion with, the posterior common ligament of the spine. It is attached, below, to the posterior surface of the body of the axis, and, becoming expanded as it ascends, is inserted into the basilar groove of the occipital bone, in front of the foramen magnum, where it becomes blended with the dura of the skull.

Relations.—By its *anterior surface* with the transverse ligament; by its *posterior surface* with the posterior common ligament.

The **lateral odontoid ligaments** (*ligamenta alaria*) (Figs. 227 and 228) are strong, rounded, fibrous cords, which arise one on either side of the upper part of

the odontoid process, and, passing obliquely upward and outward, are inserted into the rough depressions on the inner side of the condyles of the occipital bone. In the triangular interval left between these ligaments another strong fibrous cord, the **middle odontoid ligament** (*ligamentum apicis dentis*), may be seen, which passes almost perpendicularly from the apex of the odontoid process to the anterior margin of the foramen magnum, being intimately blended with the deep portion of the anterior occipito-atlantal ligament and upper fasciculus of the transverse ligament of the atlas.

Movements.—The odontoid ligaments serve to limit the extent to which rotation of the cranium may be carried; hence, they have received the name of *check ligaments*.

In addition to these ligaments, which connect the atlas and axis to the skull, the *ligamentum nuchae* must be regarded as one of the ligaments by which the vertebral column is connected with the cranium. It is described on page 272.

FIG. 228.—Median section through the occipital bone and first three cervical vertebrae with ligaments. (Spalteholz.)

Applied Anatomy.—The ligaments which unite the component parts of the vertebrae together are so strong, and these bones are so interlocked by the arrangement of their articulating processes, that *dislocation* is very uncommon, and, indeed, unless accompanied by *fracture*, seldom occurs, except in the upper part of the neck. Dislocation of the occiput from the atlas has only been recorded in one or two cases; but dislocation of the atlas from the axis, with rupture of the transverse ligament, is much more common; it is the mode in which death is produced in some cases of execution by hanging. In the lower part of the neck—that is, below the third cervical vertebra—dislocation unattended by fracture occasionally takes place.

V. Temporomandibular Articulation (*Articulatio Mandibularis*).

This is a **ginglymo-arthrodial joint**; the parts entering into its formation on each side are, *above*, the anterior part of the glenoid cavity of the temporal bone and the *eminentia articularis*; and, *below*, the condyle of the mandible. The ligaments are the following:

External Lateral.
Internal Lateral.

Stylomandibular.
Capsular.

Articular Disk.

The **external lateral ligament** (*ligamentum temporomandibulare*) (Fig. 229) is a short, thin, and narrow fasciculus, attached, *above*, to the outer surface of the zygoma and to the tubercle on its lower border; *below*, to the outer border of the neck and to the tubercle at the outer extremity of the condyle of the mandible. It is broader above than below; its fibres are placed parallel to one another,

FIG. 229.—Temporomandibular articulation.

and directed obliquely downward and backward. Externally, it is covered by the parotid gland and by the integument. Internally it is in relation with the capsular ligament, of which it is an accessory band, and from which it is not separable.

The **internal lateral ligament** (*ligamentum sphenomandibulare*) (Fig. 230) is a flat, thin band which is attached above to the spinous process of the sphenoid bone, and, becoming broader as it descends, is inserted into the margin of the dental foramen and the portion of bone, the **lingula**, which overhangs the foramen in front. Its outer surface is in relation, above, with the External pterygoid muscle; lower down it is separated from the neck of the condyle by the internal maxillary artery; and still more inferiorly, the inferior dental vessels and nerve separate it from the ramus of the mandible. The inner surface is in relation with the Internal pterygoid.

The **stylomandibular ligament** (*ligamentum stylomandibulare*) (Fig. 230) is a specialized band of the cervical fascia, which extends from near the apex of the styloid process of the temporal bone to the angle and posterior border of the ramus of the mandible, between the Masseter and Internal pterygoid muscles. This ligament separates the parotid from the submaxillary gland, and has

FIG. 230.—Temporomandibular articulation. Internal view.

attached to its inner side part of the fibres of origin of the Styloglossus muscle. Although usually classed among the ligaments of the mandible, it can be considered only as an accessory to the articulation.

The **capsular ligament** (*capsula articularis*) (Figs. 229 and 230) forms a thin and loose capsule, passing from the circumference of the glenoid cavity and the articular surface immediately in front to the upper margin of the articular disk, and from the lower margin of the articular disk to the neck of the condyle of the mandible. It consists of very thin fibres, and is complete. It forms two joint cavities, distinct from each other, and separated by the articular disk. So thin is

it that it is hardly to be considered as a distinct ligament; it is thickest at the back part, and thinnest on the inner side of the articulation.¹

The **articular meniscus** (*discus articularis*) (Fig. 231) is a thin plate of an oval form, placed horizontally between the condyle of the mandible and the glenoid cavity. Its upper surface is concavo-convex from before backward, and a little convex transversely, to accommodate itself to the form of the glenoid cavity. Its under surface, where it is in contact with the condyle, is concave. Its circumference is connected to the capsular ligament, and in front to the tendon of the External pterygoid muscle. It is thicker at its circumference, especially behind, than at its centre. The fibres of which it is composed have a concentric arrangement, more apparent at the circumference than at the centre. Its surfaces are smooth. It divides the joint into two cavities, each of which is furnished with a separate synovial membrane reflected from the capsular ligament.

FIG. 231.—Vertical section of the temporomandibular articulation.

Synovial Membranes (Fig. 231).—The synovial membranes, two in number, are placed, one above, and the other below, the articular disk. The upper one, the larger and looser of the two, is continued from the margin of the cartilage covering the glenoid cavity and eminentia

¹ Sir G. Humphry describes the internal portion of the capsular ligament separately as the short internal lateral ligament; and it certainly seems as deserving of a separate description as is the external lateral ligament.

articularis on to the upper surface of the articular disk. The *lower one* passes from the under surface of the articular disk to the neck of the condyle of the mandible, being prolonged downward a little farther behind than in front. The articular disk is sometimes perforated in its centre; the two synovial sacs then communicate with each other.

The *nerves* of this joint are derived from the auriculotemporal and masseteric branches of the inferior maxillary. The *arteries* are derived from the temporal branch of the external carotid.

Movements.—The movements possible in this articulation are very extensive. Thus, the mandible may be depressed or elevated, or it may be carried forward or backward. It must be borne in mind that there are two distinct joints in this articulation—that is to say, one between the condyle of the mandible and the articular disk, and another between the disk and the glenoid fossa; when the mandible is depressed, as in opening the mouth, the movements which take place in these two joints are not the same. In the lower compartment, that between the condyle and the articular disk, or meniscus, the movement is of a ginglymoid or hinge-like character, the condyle rotating on a transverse axis on the articular disk, or meniscus; while in the upper compartment the movement is of a gliding character, the articular disk, or meniscus, together with the condyle, gliding forward on to the *eminentia articularis*. These two movements take place simultaneously—the condyle and articular disk, or meniscus, move forward on the eminence, and at the same time the condyle revolves on the articular disk, or meniscus. In the opposite movement of shutting the mouth the reverse action takes place; the articular disk, or meniscus, glides back, carrying the condyle with it, and this at the same time revolves back to its former position. When the mandible is carried horizontally forward, as in protruding the lower incisors in front of the upper, the movement takes place principally in the upper compartment of the joint—the articular disk, or meniscus, carrying with it the condyle, glides forward on the glenoid fossa. This is because this movement is mainly effected by the External pterygoid muscles, which are inserted into both condyle and articular disk. The grinding or chewing movement is produced by the alternate movement of one condyle, with its disk, forward and backward, while the other condyle moves simultaneously in the opposite direction; at the same time the condyle undergoes a vertical rotation on its own axis on the disk in the lower compartment. One condyle advances and rotates, the other condyle recedes and rotates, in alternate succession.

The mandible is *depressed* by its own weight, assisted by the Platysma, the Digastric, the Mylohyoid, and the Geniohyoid muscles. It is *elevated* by the anterior part of the Temporal, Masseter, and Internal pterygoid muscles. It is drawn *forward* by the simultaneous action of the External pterygoid and the superficial fibres of the Masseter; and it is drawn *backward* by the deep fibres of the Masseter and the posterior fibres of the Temporal muscles. The grinding movement is caused by the alternate action of the two External pterygoids.

Surface Form.—The temporomandibular articulation is quite superficial, situated below the base of the zygoma, in front of the tragus and external auditory meatus, and behind the posterior border of the upper part of the Masseter muscle. Its exact position can be at once ascertained by feeling for the condyle of the mandible, the working of which can be distinctly felt in the movements of the mandible in opening and shutting the mouth. When the mouth is opened wide, the condyle advances out of the glenoid fossa on to the *eminentia articularis*, and a depression is felt in the situation of the joint.

Applied Anatomy.—Genuine *dislocation* of the mandible is almost always forward. Croker, King, and Theim, however, have reported posterior displacement. Dislocation is caused by violence or muscular action. When the mouth is open, the condyle is situated on the *eminentia articularis*, and any sudden violence, or even a sudden muscular spasm, as during a convulsive yawn, may displace the condyle forward into the zygomatic fossa. The displacement may be unilateral or bilateral, according as one or both of the condyles is displaced. The latter of the two is the more common. The articular disk adheres to the condyle until it passes over the *eminentia articularis*, but at this point remains behind.

Sir Astley Cooper described a condition which he termed "*subluxation*." It occurs principally in delicate women, and is believed by some to be due to the relaxation of the ligaments, permitting too free movement of the bone. Others believe it is due to displacement of the articular disk. Still others attribute the symptoms to gouty or rheumatic changes in the joint. In close relation to the condyle of the mandible is the external auditory meatus and the tympanum; any force, therefore, applied to the bone is liable to be attended with damage to these parts, or inflammation in the joint may extend to the ear, or, on the other hand, inflammation of the middle ear may involve the articulation and cause its destruction, thus leading to ankylosis of the joint. In children, arthritis of this joint may follow the exanthemata, and in adults it occurs as the result of some constitutional conditions, as rheumatism or gout. The temporomandibular joint is also occasionally the seat of *osteoarthritis*, leading to great suffering during efforts of mastication. A peculiar affection sometimes attacks the neck and condyle of the mandible, consisting in *hypertrophy* and elongation of these parts and consequent protrusion of the chin to the opposite side.

VI. Articulations of the Ribs with the Vertebrae or the Costovertebral Articulations (*Articulationes Costovertebrales*).

The articulations of the ribs with the vertebral column may be divided into two sets: (1) Those which connect the heads of the ribs with the bodies of the vertebrae—**costocentral**. (2) Those which connect the necks and tubercles of the ribs with the transverse processes—**costotransverse**.

1. COSTOCENTRAL ARTICULATIONS (*ARTICULATIONES CAPITULORUM*) (Figs. 232 and 233).

These constitute a series of arthrodial joints, formed by the articulation of the heads of the ribs with the cavities on the contiguous margins of the bodies of the

FIG. 232.—Vertebral column with ligament, from in front. (Spalteholz.)

thoracic vertebrae and the intervertebral substance between them, except in the case of the first, tenth, eleventh, and twelfth ribs, where the cavity is formed by a single vertebra. The bones are connected by the following ligaments:

Anterior Costovertebral or Stellate.	
Capsular.	Interarticular.

The **anterior costovertebral** or **stellate ligament** (*ligamentum capituli costae radiatum*) (Figs. 232 and 235) connects the anterior part of the head of each rib with the sides of the bodies of two vertebrae and the intervertebral disk between them. It consists of three flat bundles of ligamentous fibres, which are attached to the anterior part of the head of the rib, just beyond the articular

surface. The *superior* fibres pass upward to be connected with the body of the vertebra above; the *inferior* one descends to the body of the vertebra below; and the *middle* one, the smallest and least distinct, passes horizontally inward, to be attached to the intervertebral substance.

On the first rib, which articulates with a single vertebra, this ligament does not present a distinct division into three fasciculi; its fibres, however, radiate, and are attached to the body of the last cervical vertebra, as well as to the body of the vertebra with which the rib articulates. In the tenth, eleventh, and twelfth ribs also, which likewise articulate with a single vertebra, the division does not exist; but the fibres of the ligament in each case radiate and are connected with the vertebra above, as well as that with which the ribs articulate.

Relations.—In *front*, with the thoracic ganglia of the sympathetic, the pleura, and, on the right side, with the vena azygos major; *behind*, with the interarticular ligament and synovial membranes.

The **capsular ligament** (*capsula articularis*) is a thin and loose ligamentous bag, which surrounds the joint between the head of the rib and the articular cavity formed by the intervertebral disk and the adjacent vertebra. It is very thin, firmly connected with the anterior ligament, and most distinct at the upper and lower parts of the articulation. Behind, some of its fibres pass through the intervertebral foramen to the back of the intervertebral disk. This is the homologue of the *ligamentum conjugale* of some mammals, which unites the heads of opposite ribs across the back of the intervertebral disk.

The **intra-articular ligament** (*ligamentum capituli costae interarticulare*) (Figs. 233 and 234) is situated in the interior of the joint. It consists of a short band of fibres, flattened from above downward, attached by one extremity to the sharp crest which separates the two articular facets on the head of the rib, and by the other to the intervertebral disk. It divides the joint into two cavities, which have no communication with each other. For the first, tenth, eleventh, and twelfth ribs the intra-articular ligament does not exist; consequently there is but one synovial membrane.

Synovial Membranes (Figs. 233 and 234).—There are *two* synovial membranes in each of the articulations in which there is an intra-articular ligament, one on each side of this structure.

FIG. 233.—Ribs and corresponding vertebral bodies with their ligaments, viewed from the right. (Spalteholz.)

2. COSTOTRANSVERSE ARTICULATIONS (ARTICULATIONES COSTOTRANSVERSARIAE) (Fig. 234).

The articular portion of the tubercle of the rib and adjacent transverse process form an arthrodial joint.

For the *eleventh* and *twelfth ribs* this articulation is wanting.

The ligaments connecting these parts are the

Anterior Superior Costotransverse.

Posterior Costotransverse.

Middle Costotransverse (Interosseous).

Capsular.

The **anterior superior ligament** (*ligamentum costotransversarium anterius*) (Figs. 234 and 235) consists of two sets of fibres; the one (**anterior**) is attached below to the sharp crest on the upper border of the neck of each rib, and passes

FIG. 234.—Costotransverse articulation. Seen from above.

obliquely upward and outward to the lower border of the transverse process immediately above; the other (**posterior**) is attached below to the neck of the rib, and passes upward and inward to the base of the transverse process and outer border of the lower articular process of the vertebra above.

The *first rib* has no anterior costotransverse ligament. For the *twelfth rib* the ligament is absent or is a mere vestige.

Relations.—This ligament is in relation, in *front*, with the intercostal vessels and nerves; *behind*, with the Longissimus dorsi muscle. Its *internal border* is thickened and free, and bounds an aperture through which pass the posterior branches of the intercostal vessels and nerves. Its *external border* is continuous with a thin aponeurosis which covers the External intercostal muscle.

The **middle costotransverse** or **interosseous ligament** (*ligamentum collicostae*) (Fig. 234) consists of short but strong fibres which pass between the rough surface on the posterior part of the neck of each rib and the anterior surface of the adjacent transverse process. In order to fully expose this ligament, a horizontal

section should be made across the transverse process and corresponding part of the rib; or the rib may be forcibly separated from the transverse process and the fibres of the ligament put on the stretch.

For the *eleventh* and *twelfth ribs* this ligament is quite rudimentary or wanting.

The **posterior costotransverse ligament** (*ligamentum costotransversarium posterius*) (Fig. 234) is a short but thick and strong fasciculus which passes obliquely from the summit of the transverse process to the rough nonarticular portion of the tubercle of the rib.

This ligament is shorter and more oblique in the upper than in the lower ribs. Those corresponding to the superior ribs ascend, while those of the inferior ribs descend slightly.

For the *eleventh* and *twelfth ribs* this ligament is wanting.

The **capsular ligament** (*capsula articularis*) is a thin, membranous sac attached to the circumference of the articular surfaces, and enclosing a synovial membrane.

For the *eleventh* and *twelfth ribs* this ligament is absent.

Movements.—The heads of the ribs are so closely connected to the bodies of the vertebræ by the stellate and intra-articular ligaments, and the necks and tubercles of the ribs to the transverse processes, that only a slight gliding movement of the articular surfaces on each other can take place in these articulations.

The result of this gliding movement with respect to the six upper ribs consists in an elevation of the front and middle portion of the rib with a consequent enlargement of the antero-posterior diameter of the thorax, the hinder part being prevented from performing any upward movement by its close connection with the vertebral column. In this gliding movement the rib rotates on an axis corresponding to a line drawn through the two articulations, **costocentral** and **costotransverse**, which the rib forms with the vertebral column. None of the ribs lie in a truly horizontal plane; they are all directed more or less obliquely, so that their anterior extremities lie at a lower level than their posterior; this obliquity increases from the first to the seventh, and then again decreases. If we examine any one rib—say that in which there is the greatest obliquity—we shall see that it is obvious that as its sternal extremity is carried upward it must also be thrown forward; so that the rib may be regarded as a radius moving on the vertebral joint as a centre, and causing the sternal attachment to describe an arc of a circle in the vertical plane of the body. Since all the ribs are oblique and connected in front to the sternum by the flexible costal cartilages, they must have a tendency to thrust the sternum forward, and so increase the antero-posterior diameter of the thorax. With respect to the seventh, eighth, ninth, and tenth ribs, each one, besides rotating in a similar manner to the upper six, also rotates on an axis corresponding with a line drawn from the head of the rib to the sternum. By this movement an elevation of the middle portion of the rib takes place, and consequently an increase in the transverse diameter of the thorax. For the ribs not only slant downward and forward from their vertebral attachment, but they are also oblique in relation to their transverse plane—that is to say, their middle is at a lower level than

FIG. 235.—Ribs and corresponding vertebræ with ligaments, viewed from the right. (Spalteholz.)

either their vertebral or sternal extremities. It results from this that when the ribs are raised, the central portion is thrust outward, somewhat after the fashion in which the handle of a bucket is thrust away from the side when raised to a horizontal position, and the lateral diameter of the thorax is increased (see Fig. 236). The mobility of the different ribs varies greatly. The first rib is more fixed than the others, on account of the weight of the upper extremity and the strain of the ribs beneath; but on the freshly dissected thorax it moves as freely as the others. From the same causes the movement of the second rib is also not very extensive. In the other ribs this mobility increases successively down to the last two, which are very movable. The ribs are generally more movable in the female than in the male.

FIG. 236.—Diagrams showing the axis of rotation of the ribs in the movements of respiration. The one axis of rotation corresponds with the line drawn through the two articulations which the rib forms with the vertebral column (*a, b*), and the other with a line drawn from the head of the rib to the sternum (*A, B*). (From Kirke's *Handbook of Physiology*.)

VII. Costosternal Articulations (*Articulationes Sternocostales*) (Fig. 237).

The articulations of the cartilages of the true ribs with the sternum are arthrodial joints, with the exception of the first, in which the cartilage is almost always directly united with the sternum, and which must therefore be regarded as a synarthrodial articulation. The ligaments connecting them are the

Anterior Chondrosternal.
Capsular.

Posterior Chondrosternal.
Intra-articular Chondrosternal.
Chondroxiphoid.

The **anterior chondrosternal ligament** (*ligamentum sternocostale radiatum*) (Fig. 237) is a broad and thin membranous band that radiates from the front of the inner extremity of the cartilages of the true ribs to the anterior surface of the sternum. It is composed of fasciculi which pass in different directions. The *superior fasciculi* ascend obliquely, the *inferior fasciculi* pass obliquely downward, and the *middle fasciculi* pass horizontally. The superficial fibres of this ligament are the longest; they intermingle with the fibres of the ligaments above and below them, with those of the opposite side, and with the tendinous fibres of origin of the *Pectoralis major*, forming a thick fibrous membrane which covers the surface of the sternum (*membrana sterni*). This is more distinct at the lower than at the upper part.

The **capsular ligament** (*capsula articularis*) surrounds the joint formed between the cartilage of a true rib and the sternum. It is very thin, intimately blended with the anterior and posterior ligaments, and strengthened at the upper and lower part of the articulation by a few fibres which pass from the cartilage to the side of the sternum. These ligaments protect the synovial membranes.

The **posterior chondrosternal or sternocostal ligament** (*ligamentum sternocostale radiatum*), less thick and distinct than the anterior, is composed of fibres

which radiate from the posterior surface of the sternal end of the cartilages of the true ribs to the posterior surface of the sternum, becoming blended with the periosteum.

The **intra-articular chondrosternal ligament** (*ligamentum sternocostale inter-articulare*) (Fig. 233) is found between the second costal cartilage and the sternum. The cartilage of the second rib is connected with the sternum by means of an

FIG. 237.—Sternum and ribs with ligaments, from in front. In the right half of the figure the most anterior layer has been removed and the joint cavities have been opened; the parts are separated somewhat from one another on the left side. (Spalteholz.)

intra-articular ligament attached by one extremity to the cartilage of the second rib, and by the other extremity to the cartilage which unites the first and second pieces of the sternum. This articulation is provided with *two* synovial membranes. The cartilage of the third rib is also quite frequently connected with the sternum by means of an intra-articular ligament which is attached by one extremity to the cartilage of the third rib, and by the other extremity to the point of junction

of the second and third pieces of the sternum. This articulation may be provided with *two* synovial membranes. In the other joints intra-articular ligaments may exist, but they rarely completely divide the joint into two cavities.

The **anterior chondroxiphoid ligament** (*ligamentum costoxiphoides*) (Fig. 237) is a band of ligamentous fibres which connects the anterior surface of the seventh costal cartilage, and occasionally also that of the sixth, to the anterior surface of the ensiform cartilage. It varies in length and breadth in different subjects. A similar band of fibres on the internal or posterior surface, though less thick and distinct, may be demonstrated. It is spoken of as the **posterior chondroxiphoid ligament**.

Synovial Membranes (Fig. 237).—There is *no* synovial membrane between the first costal cartilage and the sternum, as this cartilage is directly continuous with the sternum. There are *two* synovial membranes, both in the articulation of the second and third costal cartilages to the sternum. There is generally *one* synovial membrane in each of the joints between the fourth, fifth, sixth, and seventh costal cartilages to the sternum; but it is sometimes absent in the sixth and seventh chondrosternal joints. Thus, there are usually *eight* synovial cavities on each side in the articulations between the costal cartilages of the true ribs and the sternum. After middle life the articular surfaces lose their polish, become roughened, and the synovial membranes appear to be wanting. In old age the articulations do not exist, the cartilages of most of the ribs becoming continuous with the sternum.

Movements.—The movements which are permitted in the chondrosternal articulations are limited to *elevation* and *depression*, and these only to a slight extent.

Articulations of the Cartilages of the Ribs with Each Other (*articulationes interchondrales*) (Fig. 237).—The contiguous borders of the sixth, seventh, and eighth, and sometimes the ninth and tenth, costal cartilages articulate with each other by small, smooth, oblong-shaped facets. Each articulation is enclosed in a thin **capsular ligament** lined by **synovial membrane**, and strengthened externally and internally by ligamentous fibres, **external** and **internal interchondral ligaments** (*ligamenta intercostalia externa et interna*), which pass from one cartilage to the other. Sometimes the fifth costal cartilage, more rarely that of the ninth, articulates, by its lower border, with the adjoining cartilage by a small oval facet; more frequently they are connected together by a few ligamentous fibres. Occasionally the articular surfaces above mentioned are wanting.

Articulations of the Ribs with their Cartilages (Fig. 237).—The outer extremity of each costal cartilage is received into a depression in the sternal ends of the ribs, and the two are held together by the periosteum. There is no real joint. Occasionally a synovial membrane exists between the first rib and the corresponding cartilage.

VIII. Articulations of the Sternum (Fig. 237)

The first piece of the sternum is united to the second either by an amphiarthrodial joint—a single piece of true fibrocartilage uniting the segments—or by a diarthrodial joint, in which each bone is clothed with a distinct lamina of hyaline cartilage, adherent on one side, free and lined with synovial membrane on the other. In the latter case the cartilage covering the gladiolus is continued without interruption on to the cartilages of the second ribs.¹ The two segments are further connected by an

Anterior Intersternal Ligament.

Posterior Intersternal Ligament.

¹ Mr. Rivington has found the diarthrodial form of joint in about one-third of the specimens examined by him; Mr. Maisonneuve more frequently. It appears to be rare in childhood, and is formed, in Mr. Rivington's opinion, from the amphiarthrodial form by absorption. The diarthrodial joint seems to have no tendency to ossify at any age, while the amphiarthrodial is more liable to do so, and has been found ossified as early as thirty-four years of age. Professor Cunningham says: "It is not usual to find the manubriogladiolar joint obliterated by the ossification of the two bony segments. Even in advanced life it remains open, and the joint partakes of the nature of an amphiarthrosis, although a joint cavity is not found under any circumstances in the plate of fibrocartilage which intervenes between the manubrium and the gladiolus."

The **anterior intersternal ligament** consists of a layer of fibres, having a longitudinal direction; it blends with the fibres of the anterior chondrosternal ligaments on both sides, and with the tendinous fibres of origin of the Pectoralis major muscle. This ligament is rough, irregular, and much thicker below than above.

The **posterior intersternal ligament** is disposed in a somewhat similar manner on the posterior surface of the articulation.

IX. Articulation of the Vertebral Column with the Pelvis.

The ligaments connecting the last lumbar vertebra with the sacrum are similar to those which connect the segments of the vertebral column with each other—viz.: (1) The continuation downward of the anterior and posterior common ligaments. (2) The intervertebral substance connecting the flattened oval surfaces of the two bones and forming an amphiarthrodial joint. (3) Ligamenta subflava, connecting the arch of the last lumbar vertebra with the posterior border of the sacral canal. (4) Capsular ligaments connecting the articulating processes and forming a double arthrodia. (5) Inter- and supraspinous ligaments.

FIG. 238.—Articulations of the pelvis and hip. Anterior view.

The two proper ligaments connecting the pelvis with the vertebral column are the lumbosacral and iliolumbar.

The **lumbosacral ligament** (Fig. 238) is a short, thick, triangular fasciculus, which is connected above to the lower and front part of the transverse process of the last lumbar vertebra; it passes obliquely outward and is attached below to the lateral surface of the base of the sacrum. It is closely blended with the anterior sacroiliac and the iliolumbar ligaments, and is to be regarded as a portion

of the iliolumbar ligament. This ligament is in relation, in *front*, with the Psoas muscle. The internal border of the lumbosacral ligament margins the foramen of the last lumbar nerve.

The **iliolumbar ligament** (*ligamentum iliolumbale*) (Fig. 238) passes horizontally outward from the apex of the transverse process of the last lumbar vertebra to the crest of the ilium immediately in front of the sacroiliac articulation. It is of a triangular form, thick and narrow internally, broad and thinner externally. It is in relation, in *front*, with the Psoas muscle; *behind*, with the muscles occupying the vertebral groove; *above*, with the Quadratus lumborum. It blends in places with the lumbosacral ligament, and its crescentic inner margin marks the limit of the foramen for the fourth lumbar nerve. These ligaments are thick prolongations from the anterior layer of the lumbar fascia.

X. Articulations of the Pelvis.

The ligaments connecting the bones of the pelvis with each other may be divided into four groups: (1) Those connecting the **sacrum** and **ilium**. (2) Those passing between the **sacrum** and **ischium**. (3) Those connecting the **sacrum** and **coccyx**. (4) Those between the two **pubic bones**.

1. ARTICULATION OF THE SACRUM AND ILIUM (ARTICULATIO SACROILIACA).

The **sacroiliac articulation** is an amphiarthrodial joint, formed between the lateral surfaces of the sacrum and ilium. The anterior or auricular portion of each articular surface is covered with a thin plate of hyaline cartilage, thicker on the sacrum than on the ilium. These are in close contact with each other, and to a certain extent united together by irregular patches of softer fibrocartilage, and at their upper and posterior part by fine fibres of interosseous fibrous tissue. Throughout a considerable part of their extent, especially in advanced life, they are not connected together, but are separated by a space containing a synovial-like fluid, and hence the joint presents the characters of a diarthrosis.

The ligaments connecting these surfaces are the

Anterior Sacroiliac.

Posterior Sacroiliac.

The **anterior sacroiliac ligament** (*ligamenta sacroiliaca anteriora*) (Fig. 238) consists of numerous thin bands which connect the anterior surfaces of the sacrum and ilium.

The **posterior sacroiliac ligament** (*ligamentum sacroiliacum posterius*) (Fig. 239) is a strong ligament, situated in a deep depression between the sacrum and ilium behind, and forming the chief bond of connection between those bones. It consists of numerous strong fasciculi which pass between the bones in various directions. The *upper part* of the ligament, the **short sacroiliac** (*ligamentum sacroiliacum posterius breve*) is nearly horizontal in direction and passes from the first and second transverse tubercles on the posterior surface of the sacrum to the rough, uneven surface at the posterior part of the inner surface of the ilium. The *lower part* (*ligamentum sacroiliacum posterius longum*), oblique in direction, is attached by one extremity to the third transverse tubercle on the posterior surface of the sacrum, and by the other to the posterior superior spine of the ilium; it is sometimes called the **oblique sacroiliac ligament**.

Surface Form.—The position of the sacroiliac joint is indicated by the posterior superior spine of the ilium. This process is immediately behind the centre of the articulation.

2. LIGAMENTS PASSING BETWEEN THE SACRUM AND ISCHIUM (Fig. 239).

The Great Sacrosciatic (Posterior).

The Small Sacrosciatic (Anterior).

The **great or posterior sacrosciatic ligament** (*ligamentum sacrotuberosum*) (Figs. 239 and 240) is situated at the lower and back part of the pelvis. It is flat, and triangular in form; narrower in the middle than at the extremities; attached by its broad base to the posterior inferior spine of the ilium, to the fourth and fifth transverse tubercles of the sacrum, and to the lower part of the lateral margin of that bone and the coccyx. Passing obliquely downward, outward, and for-

FIG. 239.—Articulations of pelvis and hip. Posterior view.

ward, it becomes narrow and thick, and at its insertion into the inner margin of the tuberosity of the ischium it increases in breadth, and is prolonged forward along the inner margin of the ramus, forming what is known as the *falciform process* of the great sacrosciatic ligament or the **falciform ligament** (*processus falciformis*). The free concave edge of this prolongation has attached to it the obturator fascia, with which it forms a kind of groove, protecting the internal pudic vessels and nerve. One of its surfaces is turned toward the perineum, the other toward the Obturator internus muscle.

Relations.—The *superficial surface* of this ligament gives origin, by its whole extent, to fibres of the Gluteus maximus muscle. Its *deep surface* is united to the lesser sacrosciatic ligament. Its *external border* forms, above, the posterior boundary of the great sacrosciatic foramen, and, below, the posterior boundary of the lesser sacrosciatic foramen. Its *lower border* forms part of the boundary of the perineum. It is pierced by the coccygeal branch of the sciatic artery and the coccygeal nerve.

The **small or anterior sacrosciatic ligament** (*ligamentum sacrospinosum*) (Figs. 239 and 240), much shorter and smaller than the preceding, is thin, triangular in form, attached by its apex to the spine of the ischium, and internally, by its broad base, to the lateral margin of the sacrum and coccyx, anterior to the attachment of the great sacrosciatic ligament, with which its fibres are intermingled.

FIG. 240.—Side view of pelvis, showing the greater and lesser sacrosciatic ligaments.

Relations.—Its *deep surface* is in relation with the Coccygeus muscle; its *superficial surface* is covered by the great sacrosciatic ligament and crossed by the internal pudic vessels and nerve. Its *superior border* forms the lower boundary of the great sacrosciatic foramen; its *inferior border*, part of the lesser sacrosciatic foramen.

These two ligaments convert the sacrosciatic notches into foramina. The **superior or great sacrosciatic foramen** (*foramen ischiadicum majus*) (Figs. 239 and 240) is bounded, in *front* and *above*, by the posterior border of the os innominatum; *behind*, by the great sacrosciatic ligament; and *below*, by the lesser sacrosciatic ligament. It is partially filled in the recent state by the Piriformis muscle, which passes through it. Above this muscle the gluteal vessels and superior gluteal nerve emerge from the pelvis, and, below it, the sciatic vessels and nerves, the internal pudic vessels and nerve, the inferior gluteal nerve, and the nerves to the Obturator internus and Quadratus femoris. The **inferior or lesser sacrosciatic foramen** (*foramen ischiadicum minus*) (Figs. 239 and 240) is bounded, in *front*, by the tuber ischii; *above*, by the spine and lesser sacrosciatic ligament; *behind*, by the greater sacrosciatic ligament. It transmits the tendon of the Obturator internus muscle, its nerve, and the internal pudic vessels and nerve.

3. ARTICULATION OF THE SACRUM AND COCCYX (SYMPHYSIS SACROCOCCYGEA).

This articulation is an amphiarthrodial joint, formed between the oval surface at the apex of the sacrum and the base of the coccyx. It is analogous to the joints between the bodies of the vertebræ. The ligaments are the

Anterior Sacrococcygeal.
Posterior Sacrococcygeal.

Lateral Sacrococcygeal.
Interposed Fibrocartilage.

The **anterior sacrococcygeal ligament** (*ligamentum sacrococcygeum anterius*) consists of a few irregular fibres which descend from the anterior surface of the sacrum to the front of the coccyx, becoming blended with the periosteum. It is a continuation of the anterior common ligament.

The **posterior sacrococcygeal ligament** (*ligamentum sacrococcygeum posterius*) (Fig. 241) is divided into two portions, the deep and the superficial. The **deep portion** (*ligamentum sacrococcygeum posterius profundum*), which is a continuation of the posterior common ligament, is a flat band of a pearly tint, which arises from the margin of the lower orifice of the sacral canal, and descends to be inserted into the posterior surface of the coccyx. This ligament completes the lower and back part of the sacral canal. Its superficial fibres are much longer than the more deeply seated. This ligament is in relation, behind, with the *Gluteus maximus*. The **superficial portion** (*ligamentum sacrococcygeum posterius superficiale*) is composed of longitudinal fibrous bands which extend from the lower portion of the middle sacral ridge to the posterior surface of the coccyx and closes partly the sacral hiatus, and of fibrous bands which extend from the sacral cornua to the coccygeal cornua. A portion of this ligament corresponds to the *ligamenta subflava* and the balance to the capsular ligament.

FIG. 241.—Ligaments between the sacrum and the coccyx. (Spalteholz.)

A **lateral sacrococcygeal** or **intertransverse ligament** (*ligamentum sacrococcygeum laterale*) (Fig. 241) connects the transverse process of the coccyx to the lower lateral angle of the sacrum on each side.

A **fibrocartilage** or **articular disk** is interposed between the contiguous surfaces of the sacrum and coccyx; it differs from that interposed between the bodies of the vertebræ in being thinner, and its central part firmer in texture. It is somewhat thicker in front and behind than at the sides. Occasionally, a synovial membrane is found and the coccyx is freely movable. This is especially the case during pregnancy.

The different **segments of the coccyx** are connected by an extension downward of the anterior and posterior sacrococcygeal ligaments, a thin annular articular disk being interposed between each of the bones. In the adult male all the pieces become ossified, but in the female this does not commonly occur until a later period of life. The separate segments of the coccyx are first united, and at a more advanced age the joint between the sacrum and coccyx is obliterated.

Movements.—The movements which take place between the sacrum and coccyx, and between the different pieces of the latter bone, are *forward* and *backward*, and are very limited. Their extent increases during pregnancy.

4. ARTICULATION OF THE PUBIC BONES (SYMPHYSIS OSSIUM PUBIS) (Figs. 238, 242).

The articulation between the pubic bones is an amphiarthrodial joint, formed by the apposition of the two oval articular surfaces of the pubic bones. The ligaments of this articulation are the

Anterior Pubic. Superior Pubic.
Posterior Pubic. Inferior Pubic.
Interpubic Disk.

The **anterior pubic ligament** (*ligamentum pubicum anterius*) (Fig. 238) consists of several superimposed layers which pass across the front of the articulation. The superficial fibres pass obliquely from one bone to the other, decussating and forming an interlacement with the fibres of the aponeurosis of the External oblique and the tendon of the Rectus abdominis muscles. The deep fibres pass transversely across the symphysis, and are blended with the interpubic disk.

FIG. 242.—Vertical section of the symphysis pubis.
Made near its posterior surface.

The **posterior pubic ligament** (*ligamentum pubicum posterius*) consists of a few thin, scattered fibres which unite the two pubic bones posteriorly.

The **superior pubic ligament** (*ligamentum pubicum superius*) (Fig. 238) is a band of fibres which connects the two pubic bones superiorly.

The **inferior pubic** or **subpubic ligament** (*ligamentum arcuatum pubis*) (Fig. 238) is a thick, triangular arch of ligamentous fibres, connecting the

two pubic bones below and forming the upper boundary of the pubic arch. Above, it is blended with the articular disk; laterally it is united with the descending rami of the pubis. Its fibres are closely connected and have an arched direction. Its lower margin is separated from the triangular ligament of the perineum by a gap, through which runs the dorsal vein of the penis.

The **interpubic disk** (*lamina fibrocartilaginea interpubica*) (Fig. 242) consists of a disk of fibrocartilage connecting the surfaces of the pubic bones in front. Each of the two surfaces is covered by a thin layer of hyaline cartilage which is firmly connected to the bone by a series of nipple-like processes which accurately fit within corresponding depressions on the osseous surfaces. These apposed cartilaginous surfaces are connected by an intermediate stratum of fibrous tissue and fibrocartilage which varies in thickness in different subjects. It often contains a cavity (*cavum articulare*) in its centre, probably formed by the softening and absorption of the fibrocartilage, since it rarely appears before the tenth year of life, and is not lined by synovial membrane. It is larger in the female than in the male. It is most frequently limited to the upper and back

part of the joint, but it occasionally reaches to the front, and may extend the entire length of the cartilage. This cavity may sometimes be demonstrated by making a vertical section of the symphysis pubis near its posterior surface (Fig. 242).

The **obturator ligament** is more properly regarded as analogous to the muscular fasciæ, with which it will be described.

ARTICULATIONS OF THE UPPER EXTREMITY.

The articulations of the upper extremity may be arranged in the following groups:

- | | |
|-------------------------------------|--|
| I. Sternoclavicular Articulation. | VII. Wrist-joint. |
| II. Acromioclavicular Articulation. | VIII. Articulations of the Carpal Bones. |
| III. Ligaments of the Scapula. | IX. Carpometacarpal Articulations. |
| IV. Shoulder-joint. | X. Metacarpophalangeal Articulations. |
| V. Elbow-joint. | XI. Articulations of the Phalanges. |
| VI. Radioulnar Articulations. | |

I. Sternoclavicular Articulation (*Articulatio Sternoclavicularis*) (Fig. 243).

The **sternoclavicular** is an arthrodial joint. The parts entering into its formation are the sternal end of the clavicle, the upper and lateral part of the first piece of the sternum, and the cartilage of the first rib. The articular surface of the

FIG. 243.—Sternoclavicular articulation. Anterior view.

sternum is covered with hyaline cartilage. The articular surface of the clavicle is much larger than that of the sternum, and invested with a layer of hyaline cartilage¹ which is considerably thicker than that on the latter bone. The ligaments of this joint are the

Capsular.
Anterior Sternoclavicular.
Posterior Sternoclavicular.

Interclavicular.
Costoclavicular.
Articular Disk.

¹According to Bruch, the sternal end of the clavicle is covered by a tissue which is rather fibrous than cartilaginous in structure.

The **capsular ligament** (*capsula articularis*) completely surrounds the articulation, consisting of fibres of varying degrees of thickness and strength. Those in front and behind are of considerable thickness, and form the anterior and posterior sternoclavicular ligaments; but those above and below, especially in the latter situation, are thin and scanty.

The **anterior sternoclavicular ligament** (*ligamentum sternoclaviculare*) (Fig. 243) is a part of the capsule. It is a broad band of fibres which covers the anterior surface of the articulation, being attached, *above*, to the upper and front part of the inner extremity of the clavicle, and, passing obliquely downward and inward, is attached, *below*, to the upper and front part of the first piece of the sternum. This ligament is covered, in *front*, by the sternal portion of the Sternomastoid and the integument; *behind*, it is in relation with the articular disk and the two synovial membranes.

The **posterior sternoclavicular ligament**, also a part of the capsule, is a band of fibres which covers the posterior surface of the articulation, being attached, *above*, to the upper and back part of the inner extremity of the clavicle, and, passing obliquely downward and inward, is attached, *below*, to the upper and back part of the first piece of the sternum. It is in relation, in *front*, with the articular disk and synovial membranes; *behind*, with the Sternohyoid and Sternothyroid muscles.

The **interclavicular ligament** (*ligamentum interclaviculare*) (Fig. 243) is a flattened band which varies considerably in form and size in different individuals; it passes in a curved direction from the upper part of the inner extremity of one clavicle to the other, and is also attached to the upper margin of the sternum. It is in relation, in *front*, with the integument; *behind*, with the Sternothyroid muscles.

The **costoclavicular or rhomboid ligament** (*ligamentum costoclaviculare*) (Fig. 243) is short, flat, and strong; it is of a rhomboid form, attached, *below*, to the upper and inner part of the cartilage of the first rib; it ascends obliquely backward and outward, and is attached, *above*, to the rhomboid depression on the under surface of the clavicle. It is in relation, in *front*, with the tendon of origin of the Subclavius; *behind*, with the subclavian vein.

The **articular disk** (*discus articularis*) (Fig. 243) is a flat and nearly circular meniscus, interposed between the articulating surfaces of the sternum and clavicle. It is attached, *above*, to the upper and posterior border of the articular surface of the clavicle; *below*, to the cartilage of the first rib, at its junction with the sternum; and by its circumference, to the anterior and posterior sternoclavicular and the interclavicular ligaments. It is thicker at the circumference, especially its upper and back part, than at its centre or below. It divides the joint into two cavities, each of which is furnished with a separate synovial membrane.

Synovial Membrane.—Of the *two* synovial membranes found in this articulation, one is reflected from the sternal end of the clavicle over the adjacent surface of the articular disk and cartilage of the first rib; the other is placed between the articular surface of the sternum and adjacent surface of the articular disk; the latter is the larger of the two.

Movements.—This articulation is the centre of the movements of the shoulder, and admits of a limited amount of motion in nearly every direction—upward, downward, backward, forward—as well as circumduction. When these movements take place in the joint, the clavicle in its motion carries the scapula with it, this bone gliding on the outer surface of the thorax. This joint therefore forms the centre from which all movements of the supporting arch of the shoulder originate, and is the only point of articulation of this part of the skeleton with the trunk. “The movements attendant on elevation and depression of the shoulder take place between the clavicle and the articular disk, the bone rotating upon the ligament on an axis drawn from before backward through its own articular facet. When the shoulder is moved forward and backward, the clavicle, with the articular disk, rolls to and fro on the articular surface of the sternum, revolving, with a gliding movement, around an axis drawn nearly vertically through the sternum. In the circumduction of the shoulder, which is compounded of these two movements, the clavicle revolves

upon the articular disk, and the latter, with the clavicle, rolls upon the sternum."¹ Elevation of the clavicle is principally limited by the costoclavicular ligament; depression by the interclavicular. The muscles which *raise* the clavicle, as in shrugging the shoulder, are the upper fibres of the Trapezius, the Levator anguli scapulae, the clavicular head of the Sternomastoid, assisted to a certain extent by the two Rhomboids, which pull the vertebral border of the scapula backward and upward, and so raise the clavicle. The *depression* of the clavicle is principally effected by gravity, assisted by the Subclavius, Pectoralis minor, and lower fibres of the Trapezius. It is drawn *backward* by the Rhomboids and the middle and lower fibres of the Trapezius; and *forward* by the Serratus magnus and Pectoralis minor.

Surface Form.—The position of the sternoclavicular joint may be easily ascertained by feeling the enlarged sternal end of the collar-bone just external to the long, cord-like, sternal origin of the Sternomastoid muscle. If this muscle is relaxed by bending the head forward, a depression just internal to the end of the clavicle, and between it and the sternum, can be felt, indicating the exact position of the joint, which is subcutaneous. When the arm hangs by the side, the cavity of the joint is V-shaped. If the arm is raised, the bones become more closely approximated, and the cavity becomes a mere slit.

Applied Anatomy.—The strength of this joint mainly depends upon its ligaments, and it is because of the ligaments and because the force of a blow is generally transmitted along the long axis of the clavicle, that dislocation so rarely occurs, and that the bone is generally broken rather than displaced. When *dislocation* does occur, the course which the displaced bone takes depends more upon the direction in which the violence was applied than upon the anatomical construction of the joint; it may be either forward, backward, or upward. A complete upward dislocation is also inward. A complete forward or backward dislocation is also inward and downward. The chief point worthy of note, as regards the construction of the joint, in regard to dislocations, is the fact that, owing to the shape of the articular surfaces being so little adapted to each other, and that the strength of the joint mainly depends upon the ligaments, the displacement when reduced is very liable to recur, and hence it is extremely difficult to keep the end of the bone in its proper place, and it may be necessary to incise the soft parts and wire the bone in place.

II. Acromioclavicular or Scapuloclavicular Articulation (*Articulatio Acromioclavicularis*) (Fig. 244).

The **acromioclavicular** is an arthrodial joint formed between the outer extremity of the clavicle and the inner margin of the acromion process of the scapula. The ligaments which surround the joint form a capsule. The ligaments of this articulation are the

Superior Acromioclavicular.	Coracoclavicular {	Trapezoid
Inferior Acromioclavicular.		and
Articular Disk.		Conoid.

The **superior acromioclavicular ligament** (*ligamentum acromioclaviculare*) (Figs 244 and 245) is a portion of the joint capsule. It is a quadrilateral band which covers the superior part of the articulation, extending between the upper part of the outer end of the clavicle and the adjoining part of the upper surface of the acromion. It is composed of parallel fibres which interlace with the aponeurosis of the Trapezius and Deltoid muscles; *below*, it is in contact with the articular disk (when it exists) and the synovial membranes.

The **inferior acromioclavicular ligament**, somewhat thinner than the preceding, and, like it, a portion of the capsule, covers the under part of the articulation and is attached to the adjoining surfaces of the two bones. It is in relation, *above*, with the synovial membranes, and in rare cases with the articular disk; *below*, with the tendon of the Supraspinatus. These two ligaments are continuous with each other in front and behind, and form a complete capsule around the joint.

¹ Humphry, On the Human Skeleton, p. 402.

The **articular disk** (*discus articularis*) is frequently absent in this articulation. When the meniscus exists it is generally incomplete and only partially separates the articular surfaces, and occupies the upper part of the articulation. More rarely it completely separates the joint into two cavities.

The Synovial Membrane.—There is usually only *one* synovial membrane in this articulation, but when a complete articular disk exists there are two synovial membranes.

The **coracoclavicular ligament** (*ligamentum coracoclaviculare*) (Figs. 244 and 245) serves to connect the clavicle with the coracoid process of the scapula. It does not properly belong to this articulation, but as it forms a most efficient means in retaining the clavicle in contact with the acromial process, it is usually described with it. It consists of two fasciculi, called the trapezoid and conoid ligaments.

FIG. 244.—The left shoulder-joint, scapuloclavicular articulations, and proper ligaments of the scapula.

The **trapezoid ligament** (*ligamentum trapezoideum*), the anterior and external fasciculus, is broad, thin, and quadrilateral; it is placed obliquely between the coracoid process and the clavicle. It is attached, *below*, to the upper surface of the coracoid process; *above*, to the oblique line on the under surface of the clavicle. Its *anterior border* is free; its *posterior border* is joined with the conoid ligament, the two forming by their junction a projecting angle.

The **conoid ligament** (*ligamentum conoideum*), the posterior and internal fasciculus, is a dense band of fibres, conical in form, the base being directed upward, the summit downward. It is attached, *below*, by its apex to a rough impression at the base of the coracoid process, internal to the trapezoid ligament; *above*, by its expanded base, to the conoid tubercle on the under surface of the clavicle, and to a line proceeding internally from it for half an inch. These ligaments are

in relation, in *front*, with the Subclavius and Deltoid; *behind*, with the Trapezius. They serve to limit rotation of the scapula, the trapezoid limiting rotation forward, and the conoid backward.

Movements.—The movements of this articulation are of two kinds: (1) A gliding motion of the articular end of the clavicle on the acromion. (2) Rotation of the scapula forward and backward upon the clavicle, the extent of this rotation being limited by the two portions of the coracoclavicular ligament.

The acromioclavicular joint has important functions in the movements of the upper extremity. It has been well pointed out by Sir George Humphry that if there had been no joint between the clavicle and scapula the circular movement of the scapula on the ribs (as in throwing both shoulders backward or forward) would have been attended with a greater alteration in the direction of the shoulder than is consistent with the free use of the arm in such position, and it would have been impossible to give a blow straight forward with the full force of the arm; that is to say, with the combined force of the scapula, arm, and forearm. "This joint," as he happily says, "is so adjusted as to enable either bone to turn in a hinge-like manner upon a vertical axis drawn through the other, and it permits the surfaces of the scapula, like the baskets in a roundabout swing, to look the same way in every position, or nearly so." Again, when the whole arch formed by the clavicle and scapula rises and falls (in elevation or depression of the shoulders), the joint between these two bones enables the scapula still to maintain its lower part in contact with the ribs.

Surface Form.—The position of the acromioclavicular joint can generally be ascertained by the slightly enlarged extremity of the outer end of the clavicle, which causes it to project above the level of the acromion process of the scapula. Sometimes this enlargement is so considerable as to form a rounded eminence, which is easily to be felt. The joint lies in the plane of a vertical line passing up the middle of the front of the arm.

Applied Anatomy.—Owing to the slanting shape of the articular surfaces of this joint, the commonest *dislocation* is the passing of the acromion process of the scapula under the outer end of the clavicle; but dislocations in the opposite direction have been described. The first form of dislocation is produced by violent force applied to the scapula so as to drive the shoulder forward. The displacement in acromioclavicular dislocation is often incomplete, on account of the strong coracoclavicular ligaments which remain untornd. The same difficulty exists, as in the sternoclavicular dislocation, in maintaining the ends of the bone in apposition after reduction, and it may become necessary to wire them in place after incision of the soft parts.

III. Proper Ligaments of the Scapula (Figs. 244, 245).

The proper ligaments of the scapula pass between portions of that bone, but are not parts of an articulation. They are the

Coracoacromial.

Superior Transverse.

Inferior Transverse.

The **coracoacromial ligament** (*ligamentum coracoacromiale*) is a strong triangular band, extending between the coracoid and acromial processes. It is attached, by its apex, to the summit of the acromion just in front of the articular surface for the clavicle, and by its broad base to the whole length of the outer border of the coracoid process. Its posterior fibres are directed inward, its anterior fibres forward and inward. This ligament completes the vault formed by the coracoid and acromion processes for the protection of the head of the humerus. It is in relation, *above*, with the clavicle and under surface of the Deltoid muscle; *below*, with the tendon of the Supraspinatus muscle, a bursa being interposed. Its *outer border* is continuous with a dense lamina that passes beneath the Deltoid upon the tendons of the Supra- and Infraspinatus muscles. This ligament is sometimes described as consisting of two marginal bands and a thinner intervening portion, the two bands being attached, respectively, to the apex and base of the coracoid process, and joining together at their attachment into the acromion process. When the Pectoralis minor is inserted, as sometimes is the case, into

the capsule of the shoulder-joint instead of into the coracoid process, it passes between these two bands, and the intervening portion is then deficient.

The **superior transverse** or **suprascapular ligament** (*ligamentum transversum scapulae superius*) (Figs. 245 and 246) converts the suprascapular notch into a

FIG. 245.—Right clavicle and scapula with ligament, from without and somewhat from in front. (Spalteholz.)

FIG. 246.—Vertical sections through the shoulder-joint, the arm being vertical and horizontal. (After Henle.)

foramen. It is a thin and flat fasciculus, narrower at the middle than at the extremities, attached by one end to the base of the coracoid process, and by the other to the inner extremity of the scapular notch. The suprascapular nerve passes through the foramen; the suprascapular vessels pass over the ligament.

An additional ligament, the **inferior transverse** or **spinoglenoid ligament** (*ligamentum transversum scapulae inferius*), is sometimes found on the scapula, stretching from the outer border of the spine to the margin of the glenoid cavity. When present, it forms an arch under which the suprascapular vessels and nerve pass as they enter the infraspinous fossa.

Movements.—The scapula is capable of being moved upward and downward, forward and backward, or, by a combination of these movements, circumducted on the wall of the thorax. The muscles which *raise* the scapula are the upper fibres of the Trapezius, the Levator anguli scapulae, and the two Rhomboids; those which *depress* it are the lower fibres of the Trapezius, the Pectoralis minor, and, through the clavicle, the Subclavius. The scapula is drawn *backward* by the Rhomboids and the middle and lower fibres of the Trapezius, and *forward* by the Serratus magnus and Pectoralis minor, assisted, when the arm is fixed, by the Pectoralis major. The mobility of the scapula is very considerable, and greatly assists the movements of the arm at the shoulder-joint. Thus, in raising the arm from the side the Deltoid and Supraspinatus can only lift it to a right angle with the trunk, the further elevation of the limb being effected by the Trapezius and Serratus magnus moving the scapula on the wall of the thorax. This mobility is of special importance in ankylosis of the shoulder-joint, the movement of this bone compensating to a very great extent for the immobility of the joint.

IV. Shoulder-Joint (*Articulatio Humeri*) (Figs. 245, 246).

The **shoulder-joint** is an enarthrodial or ball-and-socket joint. The bones entering into its formation are the large globular head of the humerus, which is received into the shallow glenoid cavity of the scapula—an arrangement which permits of very considerable movement, while the joint itself is protected against displacement by the tendons which surround it and by atmospheric pressure. The ligaments do not maintain the joint surfaces in apposition, because when they alone remain the humerus can be separated to a considerable extent from the glenoid cavity; their use, therefore, is to limit the amount of movement. *Above*, the joint is protected by an arched vault, formed by the under surfaces of the coracoid and acromion processes, and the coracoacromial ligament. The articular surfaces are covered by a layer of hyaline cartilage; that on the head of the humerus is thicker at the centre than at the circumference, the reverse being the case in the glenoid cavity. The ligaments of the shoulder are the

Capsular.
Coracohumeral.

Transverse Humeral.
Glenoid.¹

The **capsular ligament** (*capsula articularis*) (Figs. 245 and 247) completely encircles the articulation, being attached, *above*, to the circumference of the glenoid cavity beyond the glenoid ligament, *below*, to the anatomical neck of the humerus, approaching nearer to the articular cartilage above than in the rest of its extent. It is thicker above and below than elsewhere, and is remarkably loose and lax, and much larger and longer than is necessary to keep the bones in contact, allowing them to be separated from each other more than an inch—an evident provision for that extreme freedom of movement which is peculiar to this articulation. Its superficial surface is strengthened, *above*, by the Supraspinatus; *below*, by the long head of the Triceps; *behind*, by the tendons of the Infraspinatus and Teres minor; and in *front*, by the tendon of the Subscapularis. The capsular ligament usually presents three openings: One anteriorly, below the coracoid process, establishes a communication between the synovial membrane of the joint and a bursa beneath the tendon of the Subscapularis muscle.

¹ The long tendon of origin of the Biceps brachii muscle also acts as one of the ligaments of this joint. See the observations on p. 267 on the function of the muscles passing over more than one joint.

The second, which is not constant, is at the posterior part, where a communication sometimes exists between the joint and a bursal sac belonging to the *Infra-spinatus* muscle. The third is seen between the two tuberosities, for the passage of the long tendon of the *Biceps brachii* muscle. It transmits a sac-like prolongation of the synovial membrane, which ends as a blind pouch opposite the surgical neck of the bone.

The **coracohumeral ligament** (*ligamentum coracohumerale*) (Fig. 244) is a broad band which strengthens the upper part of the capsular ligament. It *arises* from the outer border of the coracoid process, and passes obliquely downward and outward to the front of the great tuberosity of the humerus, being blended with the tendon of the *Supraspinatus* muscle. This ligament is intimately united to the capsular ligament throughout the greater part of its extent.

FIG. 247.—Right shoulder-joint, frontal section, from behind. (Spalteholz.)

Supplemental Bands of the Capsular Ligament.—In addition to the coracohumeral ligament, the capsular ligament is strengthened by supplemental bands in the interior of the joint, and can be best studied by opening the capsule from behind and removing the head of the humerus. One of these bands (**Flood's ligament**) passes from the anterior edge of the glenoid cavity to the lower part of the lesser tuberosity of the humerus. It is supposed to correspond with the *ligamentum teres* of the hip-joint. A second of these bands (**Schlemm's ligament**), is situated at the lower part of the joint, and passes from the under edge of the glenoid cavity to the under part of the neck of the humerus. A third, called the **glenohumeral ligament**, is situated at the upper part of the joint. It is attached, *above*, to the apex of the glenoid cavity, close to the root of the coracoid process, and, passing downward along the inner edge of the tendon of the *Biceps brachii*, is attached, *below*, to the lesser tuberosity of the humerus, where it forms the inner boundary

of the upper part of the bicipital groove. It is a thin, ribbon-like band, occasionally quite free from the capsule.

The **transverse humeral ligament** is a prolongation of the capsular ligament. It is a broad band of fibrous tissue passing from the lesser to the greater tuberosity of the humerus, and always limited to that portion of the bone which lies above the epiphyseal line. It converts the bicipital groove into an osseoponeurotic canal, and is the homologue of the strong process of bone which connects the summits of the two tuberosities in the musk ox.

The **glenoid ligament** (*labrum glenoidale*) (Figs. 245 and 247) is a fibrocartilaginous rim, attached around the margin of the glenoid cavity. It is triangular on section, the thickest portion being fixed to the circumference of the cavity, the free edge being thin and sharp. It is continuous above with the long tendon of the Biceps muscle, which bifurcates at the upper part of the cavity into two fasciculi, and becomes continuous with the fibrous tissue of the glenoid ligament. This ligament deepens the cavity for articulation, and protects the edges of the bone.

Synovial Membrane (Fig. 247).—The synovial membrane is reflected from the margin of the glenoid cavity over the fibrocartilaginous rim surrounding it; it is then reflected over the internal surface of the capsular ligament, covers the lower part and sides of the anatomical neck of the humerus as far as the cartilage covering the head of the bone. The long tendon of the Biceps brachii, which passes through the capsular ligament, is enclosed in a tubular sheath of synovial membrane (*vagina mucosa intertubercularis*), which is reflected upon it at the point where it perforates the capsule, and is continued around it as far as the level of the surgical neck of the humerus. The tendon of the Biceps is thus enabled to traverse the articulation, but it is not contained in the interior of the synovial cavity.

Bursæ.—A large bursa, the **subscapular bursa**, exists between the joint capsule and the tendon of the Subscapularis muscle. This sac communicates with the shoulder-joint by means of an opening at the inner side of the capsular ligament. Occasionally another and smaller bursa, the **infraspinatus bursa**, exists beneath the tendon of the Infraspinatus. It communicates with the shoulder-joint by means of an opening in the outer surface of the capsule. The **subdeltoid or subacromial bursa** is placed between the under surface of the Deltoid muscle and the outer surface of the capsule. It does not communicate with the joint. The **subcutaneous acromial bursa** is between the surface and the summit of the acromion process. There is a bursa beneath the Coracobrachialis muscle, one beneath the Teres major, and one beneath the tendinous portion of the Latissimus dorsi. There is also a bursa between the tendon of insertion of the Pectoralis major muscle and the long head of the Biceps.

The **muscles** in relation with the joint are, *above*, the Supraspinatus; *below*, the long head of the Triceps; *in front*, the Subscapularis; *behind*, the Infraspinatus and Teres minor; *within*, the long tendon of the Biceps. The Deltoid is placed most externally, and covers the articulation on its outer side, as well as in front and behind.

The **arteries** supplying the joint are articular branches of the anterior and posterior circumflex, and the suprascapular.

The **nerves** are derived from the circumflex and suprascapular.

Movements.—The shoulder-joint is capable of movement in every direction, forward, backward, abduction, adduction, circumduction, and rotation. The humerus is drawn *forward* by the Pectoralis major, anterior fibres of the Deltoid, Coracobrachialis, and by the Biceps when the forearm is flexed; *backward*, by the Latissimus dorsi, Teres major, posterior fibres of the Deltoid, and by the Triceps when the forearm is extended; it is *abducted* (elevated) by the Deltoid and Supraspinatus; it is *adducted* (depressed) by the Subscapularis, Pectoralis major, Latissimus dorsi, and Teres major; it is *rotated outward* by the Infraspinatus and Teres minor; and it is *rotated inward* by the Subscapularis, Latissimus dorsi, Teres major, and Pectoralis major.

The most striking peculiarities in this joint are: (1) The large size of the head of the humerus in comparison with the depth of the glenoid cavity, even when supplemented by the glenoid ligament. (2) The looseness of the capsule of the joint. (3) The intimate connection of the capsule with the muscles attached to the head of the humerus. (4) The peculiar relation of the Biceps tendon to the joint.

It is in consequence of the relative size of the two articular surfaces that the joint enjoys such free movement in every possible direction. When these movements of the arm are arrested in the shoulder-joint by the contact of the bony surfaces and by the tension of the corresponding fibres of the capsule, together with that of the muscles acting as accessory ligaments, they can be carried considerably farther by the movements of the scapula, involving, of course, motion at

the acromio- and sternoclavicular joints. These joints are therefore to be regarded as accessory structures to the shoulder-joint.¹ The extent of these movements of the scapula is very considerable, especially in extreme elevation of the arm, which movement is best accomplished when the arm is thrown somewhat forward and outward, because the margin of the head of the humerus is by no means a true circle; its greatest diameter is from the bicipital groove downward, inward, and backward, and the greatest elevation of the arm can be obtained by rolling its articular surface in the direction of this measurement. The great width of the central portion of the humeral head also allows of very free horizontal movement when the arm is raised to a right angle, in which movement the arch formed by the acromion, the coracoid process, and the coracoacromial ligament constitutes a sort of supplemental articular cavity for the head of the bone.

The looseness of the capsule is so great that the arm will fall about an inch from the scapula when the muscles are dissected from the capsular ligament and an opening made in it to remove the atmospheric pressure. The movements of the joint, therefore, are not regulated by the capsule so much as by the surrounding muscles and by the pressure of the atmosphere—an arrangement which “renders the movements of the joint much more easy than they would otherwise have been, and permits a swinging, pendulum-like vibration of the limb when the muscles are at rest” (Humphry). The fact, also, that in all ordinary positions of the joint the capsule is not put on the stretch enables the arm to move freely in all directions. Extreme movements are checked by the tension of appropriate portions of the capsule, as well as by the interlocking of the bones. Thus it is said that “abduction is checked by the contact of the great tuberosity with the upper edge of the glenoid cavity, adduction by the tension of the coraco-humeral ligament” (Beaunis et Bouchard). Cleland² maintains that the limitations of movement at the shoulder-joint are due to the structure of the joint itself, the glenoid ligament fitting, in different positions of the elevated arm, into the anatomical neck of the humerus.

Cathcart³ has pointed out that in abducting the arm and raising it above the head, the scapula rotates throughout the whole movement with the exception of a short space at the beginning and at the end; that the humerus moves on the scapula not only from the hanging to the horizontal position, but also in passing upward as it approaches the vertical above; that the clavicle moves not only during the second half of the movement but in the first as well, though to a less extent—*i. e.*, the scapula and clavicle are concerned in the first stage as well as in the second; and that the humerus is partly involved in the second as well as chiefly in the first.

The intimate union of the tendons of the four short muscles with the capsule converts these muscles into elastic and spontaneously acting ligaments of the joint, and it is regarded as being also intended to prevent the folds into which all portions of the capsule would alternately fall in the varying positions of the joint from being driven between the bones by the pressure of the atmosphere.

The peculiar relations of the Biceps tendon to the shoulder-joint appear to subserve various purposes. In the first place, by its connection with both the shoulder and elbow the muscle harmonizes the action of the two joints, and acts as an elastic ligament in all positions, in the manner previously adverted to.⁴ Next, it strengthens the upper part of the articular cavity, and prevents the head of the humerus from being pressed up against the acromion process, when the Deltoid contracts, instead of forming the centre of motion in the glenoid cavity. By its passage along the bicipital groove it assists in rendering the head of the humerus steady in the various movements of the arm. When the arm is raised from the side it assists the Supra- and Infra-spinatus in rotating the head of the humerus in the glenoid cavity. It also holds the head of the bone firmly in contact with the glenoid cavity, and prevents its slipping over its lower edge, or being displaced by the action of the Latissimus dorsi and Pectoralis major, as in climbing and many other movements.

Surface Form.—The direction and position of the shoulder-joint may be indicated by a line drawn from the middle of the coracoacromial ligament, in a curved direction, with its convexity inward, to the innermost part of that portion of the head of the humerus which can be felt in the axilla when the arm is forcibly abducted from the side. When the arm hangs by the side, not more than one-third of the head of the bone is in contact with the glenoid cavity, and three-quarters of its circumference is in front of a vertical line drawn from the anterior border of the acromion process.

Applied Anatomy.—Owing to the construction of the shoulder-joint and the freedom of movement which it enjoys, as well as in consequence of its exposed situation, it is more frequently *dislocated* than any other joint in the body. Dislocations of the shoulder contribute about forty per cent. of the cases in tables of dislocations. *Dislocation* occurs when the arm is thrown into extreme abduction, and when, therefore, the head of the humerus presses against the lower and front part of the capsule, which is the thinnest and least supported part of the liga-

¹ See p. 299.

² *Ibid.*, vol. xviii.

³ *Journal of Anatomy and Physiology*, 1884, vol. xviii.

⁴ See p. 267.

ment. The rent in the capsule almost invariably takes place in this situation, between the tendon of the Subscapularis and the Triceps, and through it the head of the bone escapes, so that the dislocation in most instances is primarily *subglenoid*. The head of the bone does not usually remain in this situation, but generally assumes some other position, which varies according to the direction and amount of force producing the dislocation and the relative strength of the muscles in front and behind the joint. In consequence of the muscles at the back being weaker than those in front, and especially on account of the long head of the Triceps preventing the bone passing backward, dislocation forward is much more common than backward. The most frequent position which the head of the humerus ultimately assumes is on the front of the neck of the scapula, beneath the coracoid process, and hence named *subcoracoid* dislocation. Occasionally, in consequence, probably, of a greater amount of force being brought to bear on the limb, the head is driven farther inward, and rests on the upper part of the front of the thorax, beneath the clavicle (*subclavicular*). If the head of the bone passes under the Subscapularis muscle and also under the Teres major or the lower border of the Pectoralis major, the arm remains abducted, or even with the elbow raised above the head (*luxatio erecta*). Sometimes the humerus remains in the position in which it was primarily displaced, resting on the axillary border of the scapula (*subglenoid*), and rarely it passes backward and remains in the infraspinous fossa beneath the spine (*subspinous*). If dislocation frequently recurs the condition may be amended in some cases by exposing the capsule and putting tucks in it by means of sutures.

An old unreduced dislocation is sometimes treated by incising the soft parts and returning the head of the humerus into the glenoid cavity. In other cases the head of the humerus is excised. Dislocation of the long tendon of the Biceps muscle from the bicipital groove is a rare accident. When it occurs the arm is rigid in abduction, but the head of the humerus is found to be in the glenoid cavity. It is reduced by flexion of the elbow and rotation of the arm. Rupture of the long tendon of the Biceps is more common than dislocation of the tendon. After this injury the belly of the muscle is relaxed and is nearer than normal to the elbow; flexion of the forearm is much weakened, and is weaker in supination than it is in pronation. The head of the humerus passes forward and inward, and the condition is often mistaken for dislocation of the bone.

If we desire to *aspirate* the shoulder-joint, place the arm against the side, flex the forearm at a right angle to the arm, carry the forearm across the front of the thorax, and enter the trocar below the acromion (De Vos).

The shoulder-joint is sometimes the seat of all those *inflammatory affections*, both acute and chronic, which attack joints, though perhaps it suffers less frequently than some other joints of equal size and importance. *Acute synovitis* may result from injury, rheumatism, or pyemia, or may follow secondarily on the so-called acute epiphysitis of infants. It is attended with effusion into the joint, and when this occurs the capsule is evenly distended and the contour of the joint rounded. Special projections may occur at the site of the openings in the capsular ligament. Thus, a swelling may appear just in front of the joint, internal to the lesser tuberosity, from effusion into the bursa beneath the Subscapularis muscle; or, again, a swelling which is sometimes bilobed may be seen in the interval between the Deltoid and Pectoralis major muscles, from effusion into the diverticulum, which runs down the bicipital groove with the tendon of the Biceps. The effusion into the synovial membrane can be best ascertained by examination from the axilla, where a soft, elastic, fluctuating swelling can usually be felt. The bursa beneath the Deltoid is sometimes ruptured by violence, and sometimes inflames, suppurates, or becomes tuberculous.

Tuberculous arthritis not infrequently attacks the shoulder-joint, and may lead to total destruction of the articulation, when ankylosis may result or long-protracted suppuration may necessitate excision. This joint is also one of those which is most liable to be the seat of *osteoarthritis*, and may also be affected in gout and rheumatism; or in locomotor ataxia, when it occasionally becomes the seat of *Charcot's disease*.

Excision of the shoulder-joint may be required in cases of arthritis (especially the tuberculous form) which have gone on to destruction of the articulation; in *compound dislocations* and *fractures*, particularly those arising from gunshot injuries, in which there has been extensive injury to the head of the bone; in some cases of old *unreduced dislocation*, where there is much pain; and possibly in some few cases of growth connected with the upper end of the bone. The operation is best performed by making an incision from the middle of the coracoacromial ligament down the arm for about three inches; this will expose the bicipital groove and the tendon of the Biceps, which may be either divided or hooked out of the way, according as to whether it is implicated in the disease or not. The capsule is then freely opened, and the muscles attached to the greater and lesser tuberosities of the humerus divided. The head of the bone can then be thrust out of the wound and sawed off, or divided with a narrow saw *in situ* and subsequently removed. The section should be made, if possible, just below the articular surface, so as to leave the bone as long as possible. The glenoid cavity must then be examined, and gouged if carious.

V. Elbow-joint (*Articulatio Cubiti*) (Figs. 248, 249).

The elbow is a ginglymus or hinge-joint. The bones entering into its formation are the trochlea of the humerus, which is received into the greater sigmoid cavity of the ulna, and admits of the movements peculiar to such a joint—viz., flexion and extension; while the capitellum or radial head of the humerus articulates with the cup-shaped depression on the head of the radius; the circumference of the head of the radius articulates with the lesser sigmoid cavity of the ulna, allowing of the movement of rotation of the radius on the ulna, the chief action of the superior radioulnar articulation. The articular surfaces are covered by a thin layer of hyaline cartilage, and connected by a **capsular**

FIG. 248.—Left elbow-joint, showing anterior and internal ligaments.

FIG. 249.—Left elbow-joint, showing posterior and external ligaments.

Ligament (*capsula articularis*) (Fig. 250) of unequal thickness, being especially thickened on its two sides and, to a less extent, in front and behind. These thickened portions are usually described as distinct ligaments under the following names:

Anterior.
Posterior.

Internal Lateral.
External Lateral.

The **orbicular ligament** of the upper radio-ulnar articulation must also be reckoned among the ligaments of the elbow (see p. 310).

The **anterior ligament** (Fig. 248) is a broad and thin fibrous layer which covers the anterior surface of the joint. It is attached, *above*, to the front of the internal condyle and to the front of the humerus immediately above the coronoid and radial fossæ; *below*, to the anterior surface of the coronoid process of the ulna and to the orbicular ligament, being continuous on each side with the lateral ligaments. Its superficial fibres pass obliquely from the inner condyle of the humerus outward to the orbicular ligament. The middle fibres, vertical in direction, pass from the upper part of the coronoid depression and become partly blended with the preceding, but are mainly inserted into the anterior surface of the coronoid process. The deep or transverse set intersects these at right angles. This ligament is in relation, in front, with the Brachialis anticus muscle, except at its outermost part.

The **posterior ligament** (Fig. 249) is a thin and loose membranous fold, attached, *above*, to the lower end of the humerus, above and at the sides of the olecranon fossa; *below*, to the groove on the upper and outer surfaces of the olecranon. The superficial or transverse fibres pass between the adjacent margins of the olecranon fossa. The deeper portion consists of vertical fibres, some of which, thin and weak, pass from the upper part of the olecranon fossa to the margin of the olecranon; others, thicker and stronger, pass from the back of the capitellum of the humerus to the posterior border of the lesser sigmoid cavity of the ulna. This ligament is in relation, behind, with the tendon of the Triceps muscle and the Anconeus muscle.

The **internal lateral ligament** (*ligamentum collaterale ulnare*) (Fig. 248) is a thick triangular band consisting of two portions, an anterior and posterior, united by a thinner intermediate portion. The **anterior portion**, directed obliquely forward, is attached, *above*, by its apex, to the front part of the internal condyle of the humerus; and, *below*, by its broad base, to the inner margin of the coronoid process. The **posterior portion**, also of triangular form, is attached, *above*, by its apex, to the lower and back part of the internal condyle; *below*, to the inner margin of the olecranon. Between these two bands a few intermediate fibres descend from the internal condyle to blend with a transverse band of ligamentous

FIG. 250.—Right elbow-joint, cut through at right angles to the axis of the trochlea humeri, from the ulnar side. (Spalteholz.)

tissue which bridges across the notch between the olecranon and coronoid processes. This ligament is in relation, internally, with the Triceps and Flexor carpi ulnaris muscles and the ulnar nerve, and gives origin to part of the Flexor sublimis digitorum muscle.

The **external lateral ligament** (*ligamentum collaterale radiale*) (Fig. 249) is a short and narrow fibrous band less distinct than the internal, attached, *above*, to a depression below the external condyle of the humerus; *below*, to the orbicular ligament, some of its most posterior fibres passing over that ligament, to be inserted into the outer margin of the ulna. This ligament is intimately blended with the tendon of origin of the Supinator [*brevis*] muscle.

Synovial Membrane (Fig. 250).—The synovial membrane is very extensive. It covers the margin of the articular surface of the humerus, and lines the coronoid and olecranon fossæ on that bone; from these points it is reflected over the anterior, posterior, and lateral ligaments,

and forms a pouch (*recessus sacciformis*) between the lesser sigmoid cavity, the internal surface of the orbicular ligament, and the circumference of the head of the radius. Projecting into the cavity is a crescentic fold of synovial membrane, between the radius and ulna, suggesting the division of the joint into two—one the humeroradial, the other the humeroulnar.

Between the capsular ligament and the synovial membrane are three masses of fat—one, the largest, above the olecranon fossa, which is pressed into the fossa by the Triceps during flexion; a second, over the coronoid fossa; and a third, over the radial fossa. The two last-named pads are pressed into their respective fossæ during extension.

The **muscles** (Fig. 251) in relation with the joint are, in *front*, the Brachialis anticus; *behind*, the Triceps and Anconeus; *externally*, the Supinator [*brevis*] and the common tendon of origin of the Extensor muscles; *internally*, the common tendon of origin of the Flexor muscles, and the Flexor carpi ulnaris, with the ulnar nerve.

The **arteries** supplying the joint are derived from the anastomosis between the superior profunda, inferior profunda, and anastomotica magna, branches of the brachial, with the anterior, posterior, and interosseous recurrent branches of the ulnar and the recurrent branch of the radial. These vessels form a complete chain of anastomoses around the joint.

The **nerves** are derived from the ulnar as it passes between the internal condyle and the olecranon; a filament from the musculocutaneous, and two filaments from the median.

Bursæ.—The **olecranon bursa** (*bursa subcutanea olecrani*) is placed between the olecranon process and the cutaneous surface. A bursa exists between the tendon of the Biceps brachii and the tubercle of the radius (*bursa bicipitoradialis*); another between the Triceps tendon and the olecranon process (*bursa subtendinea olecrani*); a third between the cutaneous surface and the external condyle (*bursa subcutanea epicondylî humeri lateralis*); a fourth between the cutaneous surface and the internal condyle (*bursa subcutanea epicondylî humeri medialis*); and a fifth internal to the Triceps tendon at its insertion on the olecranon (*bursa intratendinea olecrani*).

Movements.—The elbow-joint comprises three different portions—viz., the joint between the ulna and humerus, that between the head of the radius and the humerus, and the superior radioulnar articulation, described below. All these articular surfaces are invested by a common synovial membrane, and the movements of the whole joint should be studied together. The combination of the movements of flexion and extension of the forearm with those of pronation and supination of the hand, which is insured by the two being performed at the same joint, is essential to the accuracy of the various minute movements of the hand.

The portion of the joint between the ulna and humerus is a simple hinge-joint, and allows

FIG. 251.—Sagittal section of the right elbow-joint, taken somewhat obliquely and seen from the radial aspect. (After Braune.)

of movements of flexion and extension only. Owing to the obliquity of the trochlear surface of the humerus, this movement does not take place in a straight line. When the forearm is extended and supinated the axis of the arm is not in the same line as the axis of the forearm, but the axis of the arm forms an angle with the axis of the forearm, and the hand, with the forearm, is directed outward. During flexion, on the other hand, the forearm and the hand tend to approach the middle line of the body, and thus enable the hand to be easily carried to the face. The shape of the articular surface of the humerus, with its prominences and depressions accurately adapted to the opposing surface of the olecranon, prevents any lateral movement. *Flexion* is produced by the action of the Biceps and Brachialis anticus, assisted by the muscles arising from the internal condyle of the humerus and by the Brachioradialis; *extension*, by the Triceps and Anconeus, assisted by the Extensors of the wrist and by the Extensor communis digitorum and Extensor minimi digiti.

The joint between the head of the radius and the capitellum or radial head of the humerus is an arthrodial joint. The bony surfaces would of themselves constitute an enarthrosis, and allow of the movement in all directions were it not for the orbicular ligament by which the head of the radius is bound down firmly to the lesser sigmoid cavity of the ulna, an arrangement which prevents any lateral separation of the two bones. It is to the same ligament that the head of the radius owes its security from dislocation, which would otherwise constantly occur as a consequence of the shallowness of the cup-like surface on the head of the radius. In fact, but for this ligament the tendon of the Biceps would be liable to pull the head of the radius out of joint.¹ In complete extension the head of the radius glides so far back on the outer condyle that its edge is plainly felt at the back of the articulation. Flexion and extension of the elbow-joint are limited by the tension of the structures on the front and back of the joint, the limitation of flexion being also aided by the soft structures of the arm and forearm coming in contact.

In combination with any position of flexion or extension the head of the radius can be rotated in the upper radioulnar joint, carrying the hand with it. The hand is directly articulated to the lower surface of the radius only, and the concave or sigmoid surface on the lower end of the radius travels around the lower end of the ulna. The latter bone is excluded from the wrist-joint (as will be seen in the sequel) by the articular disk. Thus, rotation of the head of the radius around an axis which passes through the centre of the radial head of the humerus imparts circular movement to the hand through a very considerable arc.

Surface Form.—If the forearm be slightly flexed on the arm, a curved crease or fold with its convexity downward may be seen running across the front of the elbow, extending from one condyle to the other. The centre of this fold is some slight distance above the line of the joint. The position of the radiohumeral portion of the joint can be at once ascertained by feeling for a slight groove or depression between the head of the radius and the capitellum of the humerus at the back of the articulation.

Applied Anatomy.—From the great breadth of the joint, and the manner in which the articular surfaces are interlocked, and also on account of the strong lateral ligaments and the support which the joint derives from the mass of muscles attached to each condyle of the humerus, *lateral displacement* of the bones is very uncommon, whereas *antero-posterior dislocation*, on account of the shortness of the antero-posterior diameter, the weakness of the anterior and posterior ligaments, and the want of support of muscles, much more frequently takes place, dislocation backward taking place when the forearm is in a position of extension, and forward when in a position of flexion. For, in the former position, that of extension, the coronoid process is not interlocked into the coronoid fossa, and loses its grip to a certain extent, whereas the olecranon process is in the olecranon fossa, and entirely prevents displacement forward. On the other hand, during flexion, the coronoid process is in the coronoid fossa, and prevents dislocation backward, while the olecranon loses its grip and is not so efficient, as during extension, in preventing a forward displacement. When lateral dislocation does take place, it is generally incomplete.

Dislocation of the elbow-joint is of common occurrence in children, far more common than dislocation of any other articulation. In lesions of this joint there is often very great difficulty in ascertaining the exact nature of the injury. *Sprain* of the elbow is a very common injury in childhood. Injury to the radiohumeral joint is frequently produced by lifting a child by the hand, as in swinging it over a gutter. The Supinator [brevis], which under normal circumstances would retain the head of the radius against the capitellum of the humerus, is unable to do so, the radiohumeral articulation receives the force and the orbicular ligament undergoes upward displacement, is caught between the head of the radius and the capitellum, and jams the joint. This injury is often called *subluxation of the head of the radius*.

The elbow-joint is occasionally the seat of *acute synovitis*. The synovial membrane then becomes distended with fluid, the bulging showing itself principally around the olecranon process; that is to say, on its inner and outer sides and above, in consequence of the laxness of the

¹ Humphry, op. cit., p. 419.

posterior ligament. Occasionally, a well-marked, triangular projection may be seen on the outer side of the olecranon, from bulging of the synovial membrane beneath the Anconeus muscle. Again, there is often some swelling just above the head of the radius, in the line of the radio-humeral joint. There is generally not much swelling at the front of the joint, though sometimes deep-seated fulness beneath the Brachialis anticus may be noted. When suppuration occurs the abscess usually points at one or other border of the Triceps muscle; occasionally the pus discharges itself in front, near the insertion of the Brachialis anticus muscle. *Chronic synovitis*, usually of tuberculous origin, is of common occurrence in the elbow-joint; under these circumstances the forearm tends to assume the position of semiflexion, which is that of greatest ease and relaxation of ligaments. It should be borne in mind that should ankylosis occur in this or the extended position, the limb will not be nearly so useful as if it becomes ankylosed in a position of rather less than a right angle. *Loose cartilages* are sometimes met with in the elbow-joint, not so commonly, however, as in the knee; nor do they, as a rule, give rise to such urgent symptoms. They rarely require operative interference. The elbow-joint is also sometimes affected with *osteoarthritis*, but this affection is less common in this articulation than in some other of the larger joints. *Bursitis* about the elbow, generally known as *miners' elbow*, is not uncommon.

Excision of the elbow is principally required for one of three conditions—viz., tuberculous arthritis, injury and its results, and ankylosis in a position which greatly impairs the usefulness of the limb; but may be necessary for some other rarer conditions, such as disorganizing arthritis after pyemia, unreduced dislocation, and osteoarthritis. The results of the operation are, as a rule, more favorable than those of excision of any other joint, and it is one, therefore, that the surgeon should never hesitate to perform, especially in the first three of the conditions mentioned above. The operation is best performed by a single vertical incision down the back of the joint, a transverse incision, over the outer condyle, being added if the parts are much thickened and fixed. A straight incision is made about four inches long, the mid-point of which is on a level with and a little to the inner side of the tip of the olecranon. This incision is made down to the bone, through the substance of the Triceps muscle. The operator with the point of his knife, and guarding the soft parts with his thumb-nail, separates them from the bone. In doing this there are two structures which he should carefully avoid—the ulnar nerve, which lies parallel to his incision, but a little internal, as it courses down between the internal condyle and the olecranon process, and the prolongation of the Triceps into the deep fascia of the forearm over the Anconeus muscle. Having cleared the bones and divided the lateral and posterior ligaments, the forearm is strongly flexed and the ends of the bone turned out and sawed off. The section of the humerus should be through the base of the condyles, that of the ulna and radius should be just below the level of the lesser sigmoid cavity of the ulna and the neck of the radius. In this operation the object is to obtain such fibrous union as shall allow free motion of the bones of the forearm; and, therefore, passive motion must be commenced early, that is to say, about the tenth day.

VI. Radioulnar Articulation (*Articulatio Radioulnaris*).

The articulation of the radius with the ulna is effected by ligaments which connect both extremities as well as the shafts of these bones. It may, consequently, be subdivided into three articulations: (1) The **superior radioulnar**, which is a portion of the elbow-joint; (2) the **middle radioulnar**; and (3) the **inferior radioulnar** articulations.

1. SUPERIOR ARTICULATION (*Articulatio Radioulnaris Proximalis*).

This articulation is a trochoid or pivot-joint. The bones entering into its formation are the inner side of the circumference of the head of the radius rotating within the lesser sigmoid cavity of the ulna. Its only ligament is the annular or orbicular.

The **orbicular or annular ligament** (*ligamentum annulare radii*) (Figs. 248, 249, and 252) is a strong, flat band of ligamentous fibres which surrounds the head of the radius and retains it in firm connection with the lesser sigmoid cavity of the ulna. It forms about four-fifths of an osseofibrous ring, attached by each end to the extremities of the lesser sigmoid cavity, and is smaller at the lower part of its

circumference than above, by which means the head of the radius is more securely held in its position. Its *outer surface* is strengthened by the external lateral ligament of the elbow, and affords origin to part of the Supinator [brevis] muscle. Its *inner surface* is smooth, and lined with synovial membrane. The synovial membrane is continuous with that which lines the elbow-joint.

Movements.—The movement which takes place in this articulation is limited to rotation of the head of the radius within the orbicular ligament, and upon the lesser sigmoid cavity of the ulna; the axis of rotation passes through the centre of the capitellum of the radius. Rotation forward is called *pronation*; rotation backward, *supination*. Supination is performed by the Biceps and Supinator [brevis], assisted to a slight extent by the Extensor muscles of the thumb and, in certain positions, by the Brachioradialis. Pronation is effected by the Pronator teres and Pronator quadratus, assisted, in some positions, by the Brachioradialis.

Surface Form.—The position of the superior radioulnar joint is marked on the surface of the body by the little dimple on the back of the elbow, which indicates the position of the head of the radius.

Applied Anatomy.—Dislocation of the head of the radius alone is not an uncommon accident, and occurs most frequently in young persons from falls on the hand when the forearm is extended and supinated, the head of the bone being displaced forward. It is attended by rupture of the orbicular ligament. Occasionally a peculiar injury, which is supposed to be a *subluxation*, occurs in young children in lifting them from the ground by the hand or forearm. It is believed that the head of the radius is displaced downward or the orbicular ligament upward, and the upper border of the ligament becomes folded over the head of the radius, between it and the capitellum of the humerus.

2. MIDDLE RADIOULNAR LIGAMENTS.

The interval between the shafts of the radius and ulna is occupied by two ligaments.

Oblique.

Interosseous.

The **oblique ligament** (*chorda obliqua*) (Figs. 248 and 252) is a small, flattened fibrous band which extends obliquely downward and outward from the tubercle of the ulna at the base of the coronoid process to the radius a little below the bicipital tuberosity. Its fibres run in the opposite direction to those of the

FIG. 252.—Bones of the right forearm, with their ligaments; volar aspect. (Spalteholz.)

interosseous ligament, and it appears to be placed as a substitute for it in the upper part of the interosseous interval. This ligament is sometimes wanting.

The **interosseous membrane** (*membrana interossea antebrachii*) (Fig. 252) is a broad and thin plane of fibrous tissue descending obliquely downward and inward, from the interosseous ridge on the radius to that on the ulna. It is deficient above, commencing about an inch beneath the tubercle of the radius; is broader in the middle than at either extremity; and presents an oval aperture just above its lower margin for the passage of the anterior interosseous vessels to the back of the forearm. This ligament serves to connect the bones and to increase the extent of surface for the attachment of the deep muscles. Between its upper border and the oblique ligament an interval exists through which the posterior interosseous vessels pass to the dorsum of the forearm. Two or three fibrous bands are occasionally found on the dorsal surface of this membrane which descend obliquely from the ulna toward the radius, and which have consequently a direction contrary to that of the other fibres. It is in relation, *in front*, by its upper three-fourths with the Flexor longus pollicis on the outer side, and with the Flexor profundus digitorum on the inner, lying upon the interval between which are the anterior interosseous vessels and nerve; by its lower fourth, with the Pronator quadratus; *behind*, with the Supinator [*brevis*], Extensor ossis metacarpi pollicis, Extensor brevis pollicis, Extensor longus pollicis, Extensor indicis; and, near the wrist, with the anterior interosseous artery and posterior interosseous nerve.

3. INFERIOR ARTICULATION (ARTICULATIO RADIOULNARIS DISTALIS).

This is a **pivot-joint**, formed by the sigmoid cavity at the inner side of the lower end of the radius receiving the head of the ulna. The articular surfaces are covered by a thin layer of hyaline cartilage, and connected by a capsule, portions of which are usually described as distinct ligaments. The ligaments of the articulation are:

Anterior Radioulnar.

Posterior Radioulnar.

Triangular Articular Disk.

The **anterior radioulnar ligament** (Fig. 253) is a narrow band of fibres extending from the anterior margin of the sigmoid cavity of the radius to the anterior surface of the head of the ulna.

The **posterior radioulnar ligament** (Fig. 254) extends between similar points on the posterior surface of the articulation.

The **triangular articular disk** (*discus articularis*) (Figs. 252 and 256) is triangular in shape, and is placed transversely beneath the head of the ulna, binding the lower end of this bone and the radius firmly together. Its periphery is thicker than its centre, which is thin and occasionally perforated. It is attached by its apex to a depression which separates the styloid process of the ulna from the head of that bone; and by its base, which is thin, to the prominent edge of the radius, which separates the sigmoid cavity from the carpal articulating surface. Its margins are united to the ligaments of the wrist-joint. Its *upper surface*, smooth and concave, articulates with the head of the ulna, forming an arthrodial joint; its *under surface*, also concave and smooth, forms part of the wrist-joint and articulates with the cuneiform and inner part of the semilunar bone. Both surfaces are covered by a synovial membrane—the upper surface by one peculiar to the radioulnar articulation; the under surface, by the synovial membrane of the wrist.

Synovial Membrane.—The synovial membrane (Fig. 256) of this articulation has been called, from its extreme looseness, the *membrana sacciformis*. It projects horizontally inward between the head of the ulna and the articular disk, and upward between the radius and the ulna, forming a very loose cul-de-sac (*recessus sacciformis*). The quantity of synovia which it contains is usually considerable. The inferior radioulnar joint does not communicate with the wrist-joint.

FIG. 253.—Ligaments of wrist and hand. Anterior view.

FIG. 254.—Ligaments of wrist and hand. Posterior view.

Movements.—These consist of a movement of rotation through about 160 degrees of the lower end of the radius around an axis which corresponds to the centre of the head of the ulna. When the radius rotates forward, *pronation* of the forearm and hand is the result; and when backward, *supination*. It will thus be seen that in pronation and supination of the forearm and hand the radius describes a segment of a cone, the axis of which extends from the centre of the head

of the radius to the middle of the head of the ulna. In this movement, however, the ulna is not quite stationary, but rotates a little in the opposite direction. So that it also describes the segment of a cone, though of smaller size than that described by the radius. The movement which causes this alteration in the position of the head of the ulna takes place principally at the shoulder-joint by the rotation of the humerus, but possibly also to a slight extent at the elbow-joint.¹

Surface Form.—The position of the inferior radio-ulnar joint may be ascertained by feeling for a slight groove at the back of the wrist, between the prominent head of the ulna and the lower end of the radius, when the forearm is in a state of almost complete pronation.

VII. Radiocarpal or Wrist-joint (*Articulatio Radiocarpea*) (Figs. 253, 254).

The **wrist** is a condyloid articulation. The parts entering into its formation are the lower end of the radius and under surface of the articular disk, which form together the receiving cavity, and the scaphoid, semilunar, and the cuneiform bones, which form the condyle. The articular surface of the radius and the under surface of the articular disk are the receiving cavity, forming together a transversely elliptical concave surface. The articular surfaces of the scaphoid, semilunar, and cuneiform bones form together a smooth, convex surface, the condyle, which is received into the concavity above mentioned. All the bony surfaces of the articulation are covered by hyaline cartilage, and are connected by a capsule, which is divided into the following ligaments:

External Lateral.	Anterior.
Internal Lateral.	Posterior.

The **external lateral ligament** (*ligamentum collaterale carpi radiale*) (Fig. 253) extends from the summit of the styloid process of the radius to the outer side of the scaphoid, some of its fibres being prolonged to the trapezium and annular ligament.

The **internal lateral ligament** (*ligamentum collaterale carpi ulnare*) (Fig. 253) is a rounded cord, attached, *above*, to the extremity of the styloid process of the ulna, and dividing, *below*, into two fasciculi, which are attached, one to the inner side of the cuneiform bone, the other to the pisiform bone and annular ligament.

The **anterior or volar ligament** (*ligamentum radiocarpeum volare*) (Fig. 253) is a broad, membranous band, attached, *above*, to the anterior margin of the lower end of the radius, to its styloid process, and to the ulna; its fibres pass downward and inward to be *inserted* into the palmar surface of the scaphoid, semilunar, and cuneiform bones. Some of the fibres are continued to the os magnum. In addition to this broad membrane there is a distinct rounded fasciculus, superficial to the rest, which passes from the base of the styloid process of the ulna to the semi-

FIG. 255. — Longitudinal section of the right forearm, hand, and middle finger, viewed from the ulnar aspect. (After Baurne.)

¹ See Hultkrantz, *Das Ellenbogen Gelenk und seine Mechanik*, Jena, 1897.

lunar and cuneiform bones. This ligament is perforated by numerous apertures for the passage of vessels, and is in relation, in *front*, with the tendons of the Flexor profundus digitorum and of the Flexor longus pollicis.

The **posterior or dorsal ligament** (*ligamentum radiocarpum dorsale*) (Fig. 254), thinner and weaker than the anterior, is attached, *above*, to the posterior border of the lower end of the radius; its fibres pass obliquely downward and inward, to be attached to the dorsal surface of the scaphoid, semilunar, and cuneiform bones, and are continuous with those of the dorsal carpal ligaments. This ligament is in relation, *behind*, with the Extensor tendons of the fingers.

Synovial Membrane.—The synovial membrane (Fig. 256) lines the inner surface of the ligaments above described, extending from the lower end of the radius and articular disk above to the articular surfaces of the carpal bones below. It is loose and lax, and presents numerous folds, especially behind.

The **arteries** supplying the joint are the anterior and posterior carpal branches of the radial and ulnar, the anterior and posterior interosseous, and some ascending branches from the deep palmar arch.

The **nerves** are derived from the ulnar and posterior interosseous.

Movements.—The movements permitted in this joint are *flexion*, *extension*, *abduction*, *adduction*, and *circumduction*. Its actions will be further studied with those of the carpus, with which they are combined.

Surface Form.—The line of the radiocarpal joint is on a level with the apex of the styloid process of the ulna.

Applied Anatomy.—The wrist-joint is rarely *dislocated*, its strength depending mainly upon the numerous strong tendons which surround the articulation. Its security is further provided for by the number of small bones of which the carpus is made up, and which are united by very strong ligaments. The slight movement which takes place between the several bones serves to break the jars that result from falls or blows on the hand. Dislocation backward, which is the more common dislocation, simulates to a considerable extent Colles' fracture of the radius, and is apt to be mistaken for it. The diagnosis can be easily made out by observing the relative position of the styloid processes of the radius and ulna. In the natural condition the styloid process of the radius is on a lower level—*i. e.*, nearer the ground—when the arm hangs by the side, than that of the ulna, and the same would be the case in dislocation. In Colles' fracture, on the other hand, the styloid process of the radius is on the same or even a higher level than that of the ulna.

The wrist-joint is occasionally the seat of *acute synovitis*, the result of traumatism or consequent upon rheumatic or pyemic conditions. When the synovial sac is distended with fluid, the swelling is greatest on the dorsal aspect of the wrist, and shows a general fulness, with some bulging between the tendons. The inflammation is prone to extend to the intercarpal joints and to attack also the sheaths of the tendons in the neighborhood. *Chronic inflammation* of the wrist is generally tuberculous, and often leads to similar disease in the synovial sheaths of adjacent tendons and of the intercarpal joints. The disease, therefore, when progressive, frequently leads to necrosis of the carpal bones, and the result is often unsatisfactory.

VIII. Articulations of the Carpus (*Articulatio Intercarpeae*) (Figs. 253, 254).

These articulations may be subdivided into three sets:

1. The Articulations of the First Row of Carpal Bones.
2. The Articulations of the Second Row of Carpal Bones.
3. The Articulations of the Two Rows with each other.

1. ARTICULATIONS OF THE FIRST ROW OF CARPAL BONES

These are arthrodial joints. The ligaments connecting the scaphoid, semilunar, and cuneiform bones are:

Dorsal.

Palmar.

Two Interosseous.

The **dorsal ligaments** (*ligamenta intercarpea dorsalia*) are placed transversely behind the bones of the first row; they connect the scaphoid and semilunar and the semilunar and cuneiform.

The **palmar or volar ligaments** (*ligamenta intercarpea volaria*) connect the scaphoid and semilunar and the semilunar and cuneiform bones; they are weaker than the dorsal, and placed very deeply below the anterior ligament of the wrist.

The **interosseous ligaments** (*ligamenta intercarpea interossea*) (Fig. 256) are two narrow bundles of fibrous tissue connecting the semilunar bone on one side with the scaphoid, and on the other with the cuneiform. They are on a level with the superior surfaces of these bones, and close the upper part of the spaces between them. Their upper surfaces are smooth, and form with the bones the convex articular surfaces of the wrist-joint.

The ligaments connecting the pisiform bone are:

Capsular.

Two Palmar Ligaments.

The **capsular ligament** is a thin membrane which connects the pisiform bone to the cuneiform. It is lined by a separate synovial membrane.

The **two palmar ligaments** are two strong fibrous bands which connect the pisiform to the unciform, the **pisounciate ligament** (*ligamentum pisohamatum*), and to the base of the fifth metacarpal bone, the **pisometacarpal ligament** (*ligamentum pisometacarpeum*).

2. ARTICULATIONS OF THE SECOND ROW OF CARPAL BONES.

These are also arthrodial joints. The articular surfaces are covered with hyaline cartilage, and connected by the following ligaments:

Dorsal.

Palmar.

Three Interosseous.

The **dorsal ligaments** (*ligamenta intercarpea dorsalia*) extend transversely from one bone to another on the dorsal surface, connecting the trapezium with the trapezoid, the trapezoid with the os magnum, and the os magnum with the unciform.

The **palmar ligaments** (*ligamenta intercarpea volaria*) have a similar arrangement on the palmar surface.

The **three interosseous ligaments** (*ligamenta intercarpea interossea*) (Fig. 256), much thicker than those of the first row, are placed one between the os magnum and the unciform, a second between the os magnum and the trapezoid, and a third between the trapezium and trapezoid. The first of these is much the strongest, and the third is sometimes wanting.

3. ARTICULATIONS OF THE TWO ROWS OF CARPAL BONES WITH EACH OTHER (Figs. 253, 254).

The joint between the scaphoid, semilunar, and cuneiform, and the second row of the carpus, or the **midcarpal joint**, is made up of three distinct portions; in the centre the head of the os magnum and the superior surface of the unciform articulate with the deep, cup-shaped cavity formed by the scaphoid and semilunar bones, and constitute a sort of **ball-and-socket joint**. On the outer side the trapezium and trapezoid articulate with the scaphoid, and on the inner side the unciform articulates with the cuneiform, forming **gliding joints**.

The ligaments are:

Anterior.
Posterior.

External Lateral.
Internal Lateral.

The **anterior** or **palmar ligaments** (*ligamenta intercarpea volaria*) consist of short fibres, which pass, for the most part, from the palmar surface of the bones of the first row to the front of the os magnum.

The **posterior** or **dorsal ligaments** (*ligamenta intercarpea dorsalis*) consist of short, irregular bundles of fibres passing between the bones of the first and second row on the dorsal surface of the carpus.

The **lateral ligaments** are very short; they are placed, one on the radial, the other on the ulnar side of the carpus; the *former*, the stronger and more distinct, connecting the scaphoid and trapezium, the *latter* the cuneiform and unciform; they are continuous with the lateral ligaments of the wrist-joint. In addition to these ligaments, a slender interosseous band sometimes connects the os magnum and the scaphoid.

Synovial Membrane (Fig. 256).—The synovial membrane of the carpus is very extensive; it passes from under the surface of the scaphoid, semilunar, and cuneiform bones to the upper surface of the bones of the second row, sending upward two prolongations—between the scaphoid and semilunar and the semilunar and cuneiform; sending downward three prolongations between the four bones of the second row, which are further continued onward into the carpometacarpal joints of the four inner metacarpal bones, and also for a short distance between the metacarpal bones. There is a separate synovial membrane between the pisiform and the cuneiform bones.

Movements.—The articulation of the hand and wrist, considered as a whole, is divided into three parts: (1) The radius and the articular disk, (2) the *meniscus*,¹ formed by the scaphoid, semilunar, and cuneiform, the pisiform bone having no essential part in the movements of the hand; (3) the hand proper, the metacarpal bones with the four carpal bones on which they are supported—viz., the trapezium, trapezoid, os magnum, and unciform. These three elements form two joints: (1) The superior, **wrist-joint proper**, between the meniscus and bones of the forearm; (2) the inferior, **transverse or midcarpal joint**, between the hand and meniscus.

1. The articulation between the forearm and carpus is a **true condyloid articulation**, and therefore all movements but rotation are permitted. Flexion and extension are the most extensive, and of these a greater amount of extension than flexion is permitted on account of the articulating surfaces extending farther on the dorsal than on the palmar aspect of the carpal bones. In this movement the carpal bones rotate on a transverse axis drawn between the tips of the styloid processes of the radius and ulna. A certain amount of adduction (or ulnar flexion) and abduction (or radial flexion) is also permitted. Of these movements, the former is considerably greater in extent than the latter. In these movements the carpus revolves upon an antero-posterior axis drawn through the centre of the wrist. Finally, *circumduction* is permitted by the consecutive movements of adduction, extension, abduction, and flexion, with intermediate movements between them. There is no rotation, but this is provided for by the supination and pronation of the radius on the ulna. The movement of *flexion* is performed by the Flexor carpi radialis, the Flexor carpi ulnaris, and by the Palmaris longus; *extension*, by the Extensor carpi radialis longior et brevior and the Extensor carpi ulnaris; *adduction* (ulnar flexion), by the Flexor carpi ulnaris and the Extensor carpi ulnaris; and *abduction* (radial flexion), by the Extensors of the thumb and the Extensores carpi radialis longior et brevior and the Flexor carpi radialis.

2. The chief movements permitted in the transverse or midcarpal joint are flexion, extension, and a slight amount of rotation. In *flexion* and *extension*, which are the movements most freely enjoyed, the trapezium and trapezoid on the radial side and the unciform on the ulnar side glide forward and backward on the scaphoid and cuneiform respectively, while the head of the os magnum and the superior surface of the unciform rotate in the cup-shaped cavity of the scaphoid and semilunar. Flexion at this joint is of greater range than extension. A very trifling amount of *rotation* is also permitted, the head of the os magnum rotating around a vertical axis drawn through its own centre, while at the same time a slight gliding movement takes place in the lateral portions of the joint.

¹ Called *meniscus* because the bones composing it serve the essential purposes of an articular disk.

IX. Carpometacarpal Articulations (*Articulationes Carpometacarpeae*) (Figs. 254, 255).

1. ARTICULATION OF THE METACARPAL BONE OF THE THUMB WITH THE TRAPEZIUM (*ARTICULATIO CARPOMETACARPEA POLLICIS*).

This is a joint of reciprocal reception, and enjoys great freedom of movement, on account of the configuration of its articular surfaces, which are saddle-shaped, so that, on section, each bone appears to be received into a cavity in the other, according to the direction in which they are cut. The joint is surrounded by a capsular ligament.

The **capsular ligament** is thick and fibrous, but loose, and passes from the circumference of the upper extremity of the metacarpal bones to the rough edge bounding the articular surface of the trapezium; it is thickest externally and behind, and lined with a separate synovial membrane.

Movements.—In the articulation of the metacarpal bone of the thumb with the trapezium, the movements permitted are *flexion*, *extension*, *adduction*, *abduction*, and *circumduction*. When the joint is flexed the metacarpal bone is brought in front of the palm and the thumb is gradually turned to the fingers. It is by this peculiar movement that the tip of the thumb is opposed to the other digits; for by slightly flexing the fingers the palmar surface of the thumb can be brought in contact with their palmar surfaces.

2. ARTICULATIONS OF THE METACARPAL BONES OF THE FOUR INNER FINGERS WITH THE CARPUS (*ARTICULATIONES CARPOMETACARPEAE*).

The joints formed between the carpus and four inner metacarpal bones are arthrodial joints. The ligaments are:

Dorsal.

Palmar.

Interosseous.

The **dorsal ligaments** (*ligamenta carpometacarpea dorsalis*), the strongest and most distinct, connect the carpal and metacarpal bones on their dorsal surface. The second metacarpal bone receives two fasciculi—one from the trapezium, the other from the trapezoid; the third metacarpal receives two—one from the trapezoid and one from the os magnum; the fourth, two—one from the os magnum and one from the unciform; the fifth receives a single fasciculus from the unciform bone, which is continuous with a similar ligament on the palmar surface, thus forming an incomplete capsule.

The **palmar ligaments** (*ligamenta carpometacarpea volaria*) have a somewhat similar arrangement on the palmar surface, with the exception of the third metacarpal, which has three ligaments—an *external one* from the trapezium, situated above the sheath of the tendon of the Flexor carpi radialis; a *middle one*, from the os magnum; and an *internal one*, from the unciform.

The **interosseous ligaments** consist of short, thick fibres, which are limited to one part of the carpometacarpal articulation; they connect the contiguous inferior angles of the os magnum and unciform with the adjacent surfaces of the third and fourth metacarpal bones.

Synovial Membrane.—The synovial membrane is a continuation of that between the two rows of carpal bones. Occasionally, the articulation of the unciform with the fourth and fifth metacarpal bones has a separate synovial membrane.

The synovial membranes of the wrist and carpus (Fig. 256) are thus seen to be five in number. The *first*, the *membrana sacciformis* of the inferior radioulnar articulation, passes from the lower end of the ulna to the sigmoid cavity of the radius, and lines the upper surface of the articular disk. The *second* passes from the lower end of the radius and articular disk above to the bones of the first row below. The *third*, the most extensive, passes between the contiguous margins of the two rows of carpal bones—between the bones of the second row to the carpal extremities of the four inner metacarpal bones. The *fourth* passes from the margin of the trapezium to the metacarpal bone of the thumb. The *fifth* passes between the adjacent margins of the cuneiform and pisiform bones.

Movements.—The movement permitted in the carpometacarpal articulations of the four inner fingers is limited to a slight gliding of the articular surfaces upon each other, the extent of which varies in the different joints. Thus, the articulation of the metacarpal bone of the little finger is most movable, then that of the ring finger. The metacarpal bones of the index and middle fingers are almost immovable.

FIG. 256.—Joints of the right hand, from the back of the hand. (Spalteholz.)

3. ARTICULATIONS OF THE METACARPAL BONES WITH EACH OTHER (ARTICULATIONES INTERMETACARPEAE (Figs. 254, 256).

The carpal extremities of the four inner metacarpal bones articulate with one another at each side by small surfaces covered with cartilages, and connected by dorsal, palmar, and interosseous ligaments.

The **dorsal ligaments** (*ligamenta basium oss. metacarp. dorsalia*) and **palmar ligaments** (*ligamenta basium oss. metacarp. volaria*) pass transversely from one bone to another on the dorsal and palmar surfaces.

The **interosseous ligaments** (*ligamenta basium oss. metacarp. interossea*) pass between their contiguous surfaces, just beneath their lateral articular facets.

Synovial Membrane (Fig. 256).—The synovial membrane between the lateral facets is a reflection from that between the two rows of carpal bones.

FIG. 257.—Metacarpal bones and first phalanges of the second to the fifth finger of the right hand, with ligaments, from the volar surface. (Spalteholz.)

The **transverse metacarpal ligament** (*ligamentum capitulorum oss. metacarpalium transversum*) (Fig. 257) is a narrow, fibrous band which passes transversely across the anterior surfaces of the digital extremities of the four inner metacarpal bones, connecting them. It is blended anteriorly with the palmar ligaments of the metacarpophalangeal articulations. To its posterior border is connected the fascia which covers the Interossei muscles. Its anterior surface is concave where the Flexor tendons pass over it. Behind it the tendons of the Interossei muscles pass to their insertion.

X. Metacarpophalangeal Articulations (Articulationes Metacarpophalangeae) (Figs. 257, 258).

These articulations are of the condyloid variety, formed by the reception of the rounded head of the metacarpal bone into a shallow cavity in the extremity of the first phalanx. The expansion of the Extensor communis digitorum tendon

acts as a dorsal ligament. There is a capsular ligament which at certain points has strengthening ligaments. The ligaments are:

Anterior.

Two Lateral.

The **palmar** or **vaginal ligament** (*glenoid ligament of Cruveilhier, ligamentum vaginale*) is a thick, dense, fibrous structure, placed on the palmar surface of the joint in the interval between the lateral ligaments, to which it is connected; it is loosely united to the metacarpal bone, but very firmly to the base of the first phalanx. Its palmar surface is intimately blended with the transverse metacarpal ligament, and presents a groove for the passage of the Flexor tendons, the sheath surrounding which is connected to each side of the groove. By its deep surface it forms part of the articular surface for the head of the metacarpal bone, and is lined by a synovial membrane.

The **lateral ligaments** (*ligamenta collateralia*) are strong, rounded cords placed one on each side of the joint, each being attached by one extremity to the posterior tubercle on the side of the head of the metacarpal bone, and by the other to the contiguous extremity of the phalanx.

Movements.—The movements which occur in these joints are *flexion, extension, adduction, abduction, and circumduction*; the lateral movements are very limited.

Surface Form.—The prominences of the knuckles do not correspond to the position of the joints either of the metacarpophalangeal or interphalangeal articulations. These prominences are invariably formed by the distal ends of the proximal bone of each joint, and the line indicating the position of the joint must be sought considerably in front of the middle of the knuckle. The usual rule for finding these joints is to flex the distal phalanx on the proximal one to a right angle; the position of the joint is then indicated by an imaginary line drawn along the middle of the lateral aspect of the proximal phalanx.

XI. Articulations of the Phalanges (*Articulationes Digitorum Manus*) (Fig. 258).

These are ginglymus joints. Each joint has a capsule, and certain accentuated portions are regarded as definite ligaments. These ligaments are:

Anterior or Palmar.

Two Lateral (*ligamenta collateralia*).

The arrangement of these ligaments is similar to those in the metacarpophalangeal articulations; the Extensor tendon supplies the place of a dorsal ligament.

FIG. 258.—Metacarpal bones and first phalanges of the third finger of the right hand, with ligaments, from the radial side. (Spalteholz.)

Movements.—The only movements permitted in the phalangeal joints are *flexion* and *extension*; these movements are more extensive between the first and second phalanges than between the second and third. The movement of flexion is very considerable, but extension is limited by the anterior and lateral ligaments.

ARTICULATIONS OF THE LOWER EXTREMITY.

The articulations of the lower extremity comprise the following groups:

- | | |
|---|--|
| I. The Hip-joint. | VI. The Tarsometatarsal Articulations. |
| II. The Knee-joint. | VII. Articulations of the Metatarsal |
| III. The Articulations between the
Tibia and Fibula. | Bones with each other. |
| IV. The Ankle-joint. | VIII. The Metatarsophalangeal Articulations. |
| V. The Articulations of the Tarsus. | IX. The Articulations of the Phalanges. |

I. The Hip-joint (*Articulatio Coxae*) (Figs. 259, 260).

This articulation is an enarthrodial or ball-and-socket joint, formed by the reception of the head of the femur into the cup-shaped cavity of the acetabulum. The articulating surfaces are covered by hyaline cartilage, that on the head of the femur being thicker at the centre than at the circumference, and covering the entire surface with the exception of a depression just below its centre for the attachment of the ligamentum teres; that covering the acetabulum is much thinner at the centre than at the circumference. This cartilage forms an incomplete ring of a horseshoe shape, being deficient below, where there is a circular depression, which in the recent state is occupied by a mass of fat covered by synovial membrane. The ligaments of the joints are the

Capsular.
Iliofemoral.

Teres.
Cotyloid.

Transverse.

The **capsular ligament** (*capsula articularis*) (Figs. 259 and 260) is a strong, dense, ligamentous capsule, embracing the margin of the acetabulum above and surrounding the neck of the femur below. Its *upper circumference* is attached to the acetabulum a short distance *above* and *behind* the cotyloid ligament, but in *front* it is attached to the outer margin of the ligament, and opposite to the notch, where the margin of this cavity is deficient, it is connected to the transverse ligament, and by a few fibres to the edge of the obturator foramen. Its *lower circumference* surrounds the neck of the femur, being attached, in *front*, to the spiral or anterior intertrochanteric line; *above*, to the base of the neck; *behind*, to the neck of the bone, about half an inch above the posterior intertrochanteric line. From this insertion the fibres are reflected upward over the neck of the femur, forming a sort of tubular sheath, the **cervical reflection**, which blends with the periosteum and can be traced as far as the cartilage which covers the head of the femur. On the surface of the neck of the femur some of these reflected fibres are raised into longitudinal folds, termed **retinacula**. It is much thicker at the upper and fore part of the joint, where the greatest amount of resistance is required, than below and internally, where it is thin, loose, and longer than in any other part. It consists of two sets of fibres, circular and longitudinal. The circular fibres, **zona orbicularis** (Fig. 262), are most abundant at the lower and back part of the

capsule, and form a sling or collar around the neck of the femur. Anteriorly they blend with the deep surface of the iliofemoral ligament, and through its medium reach the anterior inferior spine of the ilium. The longitudinal fibres are greatest in amount at the upper and front part of the capsule, where they form distinct bands or accessory ligaments, of which the most important is the **iliofemoral**. Other accessory bands are known as the **pubofemoral** (*ligamentum pubocapsulare*), passing from the outer portion of the horizontal pubic ramus, the iliopectineal eminence, the obturator crest and the obturator mem-

FIG. 259.—Right hip-joint, from in front. (Spalteholz.)

brane, to the front of the capsule; and the **ischiocapsular ligament** or **ligament of Bertin** (*ligamentum ischiocapsulare*), which passes from the ischium, just below the acetabulum, to blend with the circular fibres at the lower part of the joint. The *external surface* is rough, covered by numerous muscles, and separated in front from the Psoas and Iliacus muscles by a synovial bursa, which not infrequently communicates, by a circular aperture, with the cavity of the joint. It differs from the capsular ligament of the shoulder in being much less loose and lax, and in not being perforated for the passage of a tendon.

The **iliofemoral** or **Y-ligament** or **ligament of Bigelow** (*ligamentum iliofemorale*) (Figs. 262 and 263) is an accessory band of fibres extending obliquely across the front of the joint; it is intimately connected with the capsular ligament, and serves to strengthen it in this situation. It is attached, *above*, to the lower part of the anterior inferior spine of the ilium and the adjacent rim of the acetabulum; and, diverging below, forms two bands, of which one passes downward to be inserted into the lower part of the anterior intertrochanteric line; the other passes downward

FIG. 260.—Right hip-joint, from behind. (The joint capsule, except for the strengthening ligaments, has been removed. (Spalteholz.)

and outward to be inserted into the upper part of the same line and the adjacent part of the neck of the femur. Between the two bands is a thinner part of the capsule. Sometimes there is no division, but the ligament spreads out into a flat, triangular band, which is attached below into the whole length of the anterior intertrochanteric line. This ligament is frequently called the **Y-shaped ligament of Bigelow**; and the outer or upper of the two bands is sometimes described as a separate ligament, under the name of the **iliotrochanteric ligament**.

The **ligamentum teres** (*ligamentum teres femoris*) (Figs. 262 and 263) is a triangular band implanted by its apex into the depression a little behind and below the centre of the head of the femur, and by its broad base into the margins of the cotyloid notch, where it blends with the transverse ligament. It is formed of white fibrous connective tissue, surrounded by a tubular sheath of synovial membrane. Sometimes only the synovial fold exists. Very rarely it is absent. The ligament is made tense when the hip is semiflexed, and the limb adducted and rotated outward; it is, on the other hand, relaxed when the limb is abducted. It has, however, but little influence as a ligament, and though it may to a certain extent limit movement, it would appear to be merely a "vestigial and practically useless ligament."¹

FIG. 261.—Right hip-joint from the mesal side. (The bottom of the acetabulum has been chiselled away sufficiently to make the head of the femur visible.) (Spalteholz.)

The **cotyloid ligament** (*labrum glenoidale*) (Fig. 264) is a fibrocartilaginous rim attached to the margin of the acetabulum, the cavity of which it deepens; at the same time it protects the edges of the bone and fills up the inequalities on its surface. It bridges over the notch as the **transverse ligament of the acetabulum**, and thus forms a complete circle, which closely surrounds the head of the femur, and assists in holding it in its place. It is prismoid on section, its base being attached to the margin of the acetabulum and its opposite edge being free and sharp. Its two surfaces are invested by synovial membrane, the external one being in contact with the capsular ligament, the internal one being inclined inward, so as to narrow the acetabulum and embrace the cartilaginous surface of the head of the femur. It is much thicker above and behind than below and in front,

¹J. Bland Sutton, *Ligaments: Their Nature and Morphology*, 1887.

and consists of close, compact fibres, which arise from different points of the circumference of the acetabulum and interlace with each other at very acute angles.

The **transverse ligament of the acetabulum** (*ligamentum transversum acetabuli*) (Figs. 261 and 264) is in reality a portion of the cotyloid ligament, though differing from it in having no cartilage cells among its fibres. It consists of strong, flattened fibres, which cross the notch at the lower part of the acetabulum and convert it into a foramen. Thus an interval is left beneath the ligament for the passage of nutrient vessels to the joint.

FIG. 262.—The right hip-joint, seen from before. (Toldt.)

The **synovial membrane** (Figs. 262 and 263) is very extensive. Commencing at the margin of the cartilaginous surface of the head of the femur, it covers all that portion of the neck which is contained within the joint; from the neck it is reflected on the internal surface of the capsular ligament; it covers both surfaces of the cotyloid ligament and the mass of fat contained in the depression at the bottom of the acetabulum, and it is prolonged as far as the head of the femur in the form of a tubular sheath around the ligamentum teres. It sometimes communicates through an aperture in the capsular ligament between the inner band of the Y-shaped ligament and the pubofemoral ligament with a bursa situated on the under surface of the Iliopsoas muscle.

The **muscles** in relation with the joint (Fig. 264) are, in *front*, the Psoas and Iliacus, separated from the capsular ligament by a synovial bursa; *above*, the reflected head of the Rectus femoris and Gluteus minimus, the latter being closely adherent to the capsule; *internally*, the Obturator externus and Pectineus; *behind*, the Piriformis, Gemellus superior, Obturator internus, Gemellus inferior, Obturator externus, and Quadratus femoris.

The **arteries** supplying the joint are derived from the obturator, sciatic, internal circumflex, and gluteal.

The **nerves** are articular branches from the sacral plexus, great sciatic, obturator, accessory obturator, and a filament from the branch of the femoral (anterior crural) supplying the Rectus femoris.

Bursæ.—Numerous bursæ exist in the neighborhood of the hip-joint. Some anatomists have counted twenty-one (Synnestredt). The chief ones are: (1) The **iliopectineal bursa** (*bursa iliopectinea*) (Fig. 265), between the Iliopsoas tendon and the capsule of the joint. This bursa often communicates with the hip-joint. (2) The **subtendinous iliac bursa** (*bursa iliaca subtendinea*), between the tendon of the Psoas and Iliacus and the lesser trochanter. (3) The **ischio-**

FIG. 263.—Right hip-joint. Frontal section. Posterior half, viewed from in front. The joint surfaces have been somewhat pulled apart. (Spalteholz.)

gluteal bursa (*bursa ischiadica m. glutæi maximi*), between the Gluteus maximus muscle and the tuberosity of the ischium (not constant). (4) The **bursa of the greater trochanter** (*bursa trochanterica m. glutæi maximi*), between the greater trochanter and the Gluteus maximus muscle near the muscular insertion. (5) Two or three **gluteofemoral bursæ** (*bursæ glutæofemorales*) below. (6) The **obturator bursa** (*bursa m. obturatorii interni*), between the margin of the great sacrosclatic notch and the tendon of the Obturator internus muscle. (7) The **subcutaneous trochanteric bursa** (*bursa trochanterica subcutanea*), between the cutaneous surface and the great trochanter. Besides these there is a bursa between the greater trochanter and the anterior part of the Gluteus medius; between the greater trochanter and the posterior part of the Gluteus medius; between the greater trochanter and the Gluteus minimus; beneath the Piriformis

muscle; between the lesser trochanter and the Quadratus femoris muscle; and there are bursæ beneath the Biceps femoris muscle.

Movements.—The movements of the hip are very extensive, and consist of *flexion*, *extension*, *adduction*, *abduction*, *circumduction*, and *rotation*.

The hip-joint presents a very striking contrast to the shoulder-joint in the much more complete mechanical arrangements for its security and for the limitation of its movements. In the shoulder, as we have seen, the head of the humerus is not adapted at all in size to the glenoid cavity, and is hardly restrained in any of its ordinary movements by the capsular ligament. In the hip-joint, on the contrary, the head of the femur is closely fitted to the acetabulum for a distance extending over nearly half a sphere, and at the margin of the bony cup it is still more closely embraced by the cotyloid ligament, so that the head of the femur is held in its place by that ligament even when the fibres of the capsule have been quite divided (Humphry). The anterior portion of the capsule, described as the iliofemoral ligament, is the strongest of all the ligaments in the body, and is put on the stretch by any attempt to extend the femur beyond a straight line with the trunk. That is to say, this ligament is the chief agent in maintaining the erect position without muscular fatigue; for a vertical line passing through the

FIG. 264.—Relation of muscles to the capsule of the hip-joint. (From a drawing by Mr. F. A. Barton.)

centre of gravity of the trunk falls behind the centres of rotation in the hip-joint, and therefore the pelvis tends to fall backward, but is prevented by the tension of the iliofemoral and capsular ligaments. The security of the joint may be also provided for by the two bones being directly united through the ligamentum teres; but it is doubtful whether this so-called ligament can have much influence upon the mechanism of the joint. *Flexion* of the hip-joint is arrested by the soft parts of the thigh and abdomen being brought into contact when the leg is flexed on the thigh; and by the action of the Hamstring muscles when the leg is extended.¹ Extension is arrested by the tension of the iliofemoral ligament and the front of the capsule; *adduction*, by the thighs coming into contact; *adduction with flexion*, by the outer band of the iliofemoral ligament, and the outer part of the capsular ligament; *abduction*, by the inner band of the iliofemoral ligament and the pubofemoral band; *rotation outward*, by the outer band of the iliofemoral ligament; and *rotation inward*, by the ischiocapsular ligament and the hinder part of the capsule. The muscles which *flex* the femur on the pelvis are the Psoas, Iliacus, Rectus femoris, Sartorius, Pectineus, Adductor longus and brevis, and the anterior fibres of the Gluteus medius

¹ The hip-joint cannot be completely flexed, in most persons, without at the same time flexing the knee, on account of the shortness of the Hamstring muscles.—Cleveland, Jour. of Anat. and Physiol., No. 1, Old Series, p. 87.

and minimus. *Extension* is mainly performed by the Gluteus maximus, assisted by the Hamstring muscles. The thigh is *adducted* by the Adductores magnus, longus, and brevis, the Pectineus, the Gracilis, and the lower part of the Gluteus maximus, and *abducted* by the Gluteus medius and minimus and the upper part of the Gluteus maximus. The muscles which *rotate* the thigh *inward* are the anterior fibres of the Gluteus medius, the Gluteus minimus, and the Tensor fasciae femoris; while those which rotate it *outward* are the posterior fibres of the Gluteus medius, the Piriformis, Obturator externus and internus, Gemellus superior and inferior, Quadratus femoris, Iliacus, Gluteus maximus, the three Adductors, the Pectineus, and the Sartorius.

Surface Form.—A line drawn from the anterior superior spinous process of the ilium to the most prominent part of the tuberosity of the ischium (*Nélaton's line*) runs through the centre of the acetabulum, and would, therefore, indicate the level of the hip-joint; or, in other words, the upper border of the great trochanter, which lies on *Nélaton's line*, is on a level with the centre of the hip-joint.

Applied Anatomy.—Inflammation of *bursæ* about the hip-joint gives rise to confusing symptoms, and is not uncommonly mistaken for hip-joint disease.

FIG. 265.—Nélaton's line and Bryant's triangle.

In *dislocation of the hip* "the head of the thigh bone may rest at any point around its socket" (Bryant); but whatever position the head ultimately assumes, the primary displacement is generally downward and inward, the capsule giving way at its weakest—that is, its lower and inner—part. The situation that the head of the bone subsequently assumes is determined by the degree of flexion or extension, and of outward or inward rotation of the thigh at the moment of luxation, influenced, no doubt, by the iliofemoral ligament, which is not easily ruptured. When, for instance, the head is forced backward, this ligament forms a fixed axis, around which the head of the bone rotates, and the head is thus driven on to the dorsum of the ilium. The iliofemoral ligament also influences the position of the thigh in the various dislocations: in the dislocations backward it is tense, and produces inversion of the limb; in the dislocation on to the pubes it is relaxed, and therefore allows the External rotators to evert the thigh; while in the thyroid dislocation it is tense and produces flexion. The muscles inserted into the upper part of the femur, with the exception of the Obturator internus, have very little direct influence in determining the position of the bone. Bigelow has endeavored to show that the Obturator internus is the principal agent in determining whether in the backward dislocations the head of the bone shall be ultimately lodged on the dorsum of the ilium or in or near the sciatic notch. In both dislocations the head passes, in the first instance, in the same direction; but, as Bigelow

asserts, in the displacement on to the dorsum, the head of the bone travels up behind the acetabulum, in front of the muscle; while in the dislocation into the sciatic notch, the head passes behind the muscle, and is therefore prevented from reaching the dorsum, in consequence of the tendon of the muscle arching over the neck of the bone, and so remains in the neighborhood of the sciatic notch. Bigelow, therefore, distinguishes these two forms of dislocation by describing them as dislocations backward, "above and below," the Obturator internus.

The iliofemoral ligament is rarely torn in dislocations of the hip, and this fact is taken advantage of by the surgeon in reducing these dislocations by manipulation. It is made to act as a fulcrum to a lever of which the long arm is the shaft of the femur, and the short arm the neck of the bone.

The hip-joint is rarely the seat of *acute synovitis* from injury, on account of its deep position and its thick covering of soft parts. *Acute inflammation* may, and does, frequently occur as the result of constitutional conditions, as rheumatism, pyemia, etc. When, in these cases, effusion takes place, and the joint becomes distended with fluid, the swelling is not very easy to detect on account of the thickness of the capsule and the depth of the articulation. It is principally to be found on the front of the joint, just internal to the iliofemoral ligament; or behind, at the lower and back part. In these two places the capsule is thinner than elsewhere. Disease of the hip-joint is much more frequently of a chronic character and is usually, of *tuberculous* origin. It begins either in the bones or in the synovial membrane, more frequently in the former, and probably, in most cases, in the growing, highly vascular tissue in the neighborhood of the epiphyseal cartilage. In this respect it differs very materially from the tuberculous arthritis of the knee, where the disease often commences in the synovial membrane.

In *chronic hip disease* the affected limb assumes an altered position, the cause of which it is important to understand. In the early stage of a typical case the limb is flexed, abducted, and rotated outward. In this position all the ligaments of the joint are relaxed—the front of the capsule by flexion; the outer band of the iliofemoral ligament by abduction; and the inner band of this ligament and the back of the capsule by rotation outward. It is, therefore, the position of the greatest ease. The condition is not quite obvious at first upon examining a patient. If the patient is laid in the supine position, the affected limb will be found to be extended and parallel with the other. But it will be found that the pelvis is tilted downward on the diseased side and the limb apparently longer than its fellow, and that the lumbar portion of the vertebral column is arched forward (*lordosis*). If now the thigh is abducted and flexed, the tilting downward and the arching forward of the pelvis disappears. The condition is thus explained. A limb which is flexed and abducted is obviously useless for progression, and, to overcome the difficulty, the patient depresses the affected side of his pelvis in order to produce parallelism of his limbs, and at the same time rotates his pelvis on its transverse horizontal axis, so as to direct the limb downward instead of forward. In the latter stages of the disease the limb becomes flexed, adducted, and inverted. The position probably depends upon the muscular action, at all events as regards the adduction. The Adductor muscles are supplied by the obturator nerve, which also largely supplies the joint. These muscles are therefore thrown into reflex action by the irritation of the peripheral terminations of this nerve in the inflamed articulation. *Osteoarthritis* is not uncommon in the hip-joint, and it is said to be more common in the male than in the female, in whom the knee-joint is more frequently affected. It is a disease of middle age or more advanced period of life.

Congenital dislocation is more commonly met with in the hip-joint than in any other articulation. The displacement usually takes place on to the dorsum ilii. It gives rise to extreme lordosis, and a waddling gait is noticed as soon as the child commences to walk.

Excision of the hip may be required for disease or for injury, especially for gunshot wound. It may be performed either by an anterior or an external incision. The former one entails less interference with important structures, especially muscles, than the posterior one, but permits of less efficient drainage. In the operation in front the surgeon makes an incision three or four inches in length, starting immediately below and external to the anterior superior spinous process of the ilium, downward and inward between the Sartorius and Tensor fasciæ femoris, to the neck of the bone, dividing the capsule at its upper part. A narrow-bladed saw now divides the neck of the femur, and the head of the bone is extracted with sequestrum forceps. All diseased tissue is carefully removed with a sharp spoon or scissors, and the cavity thoroughly flushed with a hot aseptic fluid.

The external method consists in making an incision three or four inches long, commencing midway between the top of the great trochanter and the anterior superior spine, and ending over the shaft, just below the trochanter. The muscles are detached from the great trochanter, and the capsule opened freely. The head and neck are freed from the soft parts and the bone sawed through just below the top of the trochanter with a narrow saw. The head of the bone is then levered out of the acetabulum. In both operations, if the acetabulum is eroded, it must be freely gouged.

II. The Knee-joint (*Articulatio Genu*).

The **knee-joint** was formerly described as a ginglymus or hinge-joint, but is really of a much more complicated character. It must be regarded as consisting of *three* articulations in one—one between each condyle of the femur and the corresponding tuberosity of the tibia, which are condyloid joints, and one between the patella and the femur, which is partly arthroidal, but not completely so, since the articular surfaces are not mutually adapted to each other, so that the movement is not a simple gliding one. This view of the construction of the knee-joint receives confirmation from the study of the articulation in some of the lower mammals, where three synovial membranes are sometimes found, corresponding to these three subdivisions, either entirely distinct or only connected by small communications. This view is further rendered probable by the existence of the two crucial ligaments within the joint, which must be regarded as the external and internal lateral ligaments of the inner and outer joints respectively. The existence of the ligamentum mucosum would further indicate a tendency to separation of the synovial cavity into two minor sacs, one corresponding to each joint.

The bones entering into the formation of the knee-joint are the condyles of the femur *above*, the head of the tibia *below*, and the patella *in front*. The bones are connected by ligaments, some of which are placed on the exterior of the joint, while others occupy its interior.

The **capsular ligament** (*capsula articularis*) (Fig. 266) consists of an exceedingly thin, but strong, fibrous membrane, which is strengthened in almost its entire extent by heavy bands which are inseparably connected with it. *In front* it blends with and forms part of the lateral patellar ligaments and fills in the interval between the anterior and lateral ligaments of the joints, with which latter structures it is closely connected. It is deficient *above* the joint and beneath the tendon of the Quadriceps extensor. *Behind*, it is formed chiefly of vertical fibres, which arise above from the condyles and intercondyloid notch of the femur, and is connected *below* with the back part of the head of the tibia, being closely united with the origins of the Gastrocnemius, Plantaris, and Popliteus muscles. It passes in front of, but is inseparably connected with, the posterior ligament.

The **anterior ligament**, or **ligamentum patellae** (Figs. 266, 270, and 271), is the central portion of the common tendon of the Extensor muscles of the thigh, which is continued from the patella to the tubercle of the tibia, supplying the place of an anterior ligament. It is a strong, flat, ligamentous band about three inches in length, attached, *above*, to the apex of the patella and to the rough depression on its posterior surface; *below*, to the lower part of the tubercle of the tibia, its superficial fibres being continuous over the front of the patella with those of the tendon of the Quadriceps extensor. The lateral portions of the tendon of the Extensor muscles in conjunction with the fascia lata pass down on either side of the patella, and are attached to the tibia on either side of the tubercle; these are termed **lateral patellar ligaments** (*retinaculum patellae mediale et laterale*), and merge into the capsule. The posterior surface of the ligamentum patellae is separated,

above, from the synovial membrane by a fold of fat; below, it is separated from the head of the tibia by a synovial bursa.

The **posterior ligament** (*ligamentum popliteum obliquum*) (Fig. 266) is a broad, flat, fibrous band, formed of fasciculi separated from one another by apertures for the passage of vessels and nerves. It is attached, above, to the upper margin of the intercondyloid notch of the femur, and, below, to the posterior margin of the head of the tibia. Superficial to the main part of the ligament and forming a portion of it is a strong fasciculus derived from the tendon of the Semimembranosus; it passes from the back part of the inner tuberosity of the tibia obliquely upward and outward to the back part of the outer condyle of the femur and blends with the posterior ligament. This expansion from the tendon of the Semimem-

FIG. 266.—Right knee-joint. Anterior view.

FIG. 267.—Right knee-joint. Posterior view.

branosus muscle is called the **posterior ligament of Winslow** (*ligamentum posticum Winslowii*). The posterior ligament forms part of the floor of the popliteal space, and the popliteal artery rests upon it.

The **internal lateral ligament** (*ligamentum collaterale tibiale*) (Figs. 266 and 267) is a broad, flat, membranous band, thicker behind than in front, and situated nearer to the back than the front of the joint. It is attached, above, to the inner tuberosity of the femur; below, to the inner tuberosity and inner surface of the shaft of the tibia to the extent of about two inches. It is crossed, at its lower part, by the tendons of the Sartorius, Gracilis, and Semitendinosus muscles, a synovial bursa being interposed. Its deep surface covers the anterior portion of the tendon of the Semimembranosus, with which it is connected by a few fibres, and the inferior internal articular vessels and nerve; it is intimately adherent to the internal semilunar fibrocartilage.

The **external lateral** or **long external lateral ligament** (*ligamentum collaterale fibulare*) (Figs. 267 and 271) is a strong, rounded, fibrous cord situated nearer to the back than the front of the joint. It is attached, *above*, to the back part of the outer tuberosity of the femur; *below*, to the outer part of the head of the fibula. Its *outer surface* is covered by the tendon of the Biceps femoris, which divides at its insertion into two parts, separated by the ligament. The ligament has, passing beneath it, the tendon of the Popliteus muscle and the inferior external articular vessels and nerve.

The **short external lateral ligament** (*ligamentum laterale externum breve seu posticum*) (Fig. 267) is not a constant structure. It is an accessory bundle of fibres placed behind and parallel with the preceding, attached, *above*, to the lower and back part of the outer tuberosity of the femur; *below*, to the summit of the styloid process of the fibula. This ligament is intimately connected with the capsular ligament, and has, passing beneath it, the tendon of the Popliteus muscle and the inferior external articular vessels and nerve.

The **crucial ligaments** (*ligamenta cruciata genu*) (Figs. 268 and 269) are two interosseous ligaments of considerable strength situated in the interior of the joint, nearer its posterior than its anterior part. They are called crucial because they cross each other somewhat like the lines of the letter X; and have received the names anterior crucial and posterior crucial, from the position of their attachment to the tibia.

The **anterior or external crucial ligament** (*ligamentum cruciatum anterius*) (Fig. 268) is attached to the depression in front of the spine of the tibia, being blended with the anterior extremity of the external semilunar fibrocartilage, and, passing obliquely upward, backward, and outward, is inserted into the inner and back part of the outer condyle of the femur.

The **posterior or internal crucial ligament** (*ligamentum cruciatum posterius*) is stronger, but shorter and less oblique in its direction than the anterior. It is attached to the back part of the depression behind the

FIG. 268.—Right knee-joint. Showing internal ligaments.

FIG. 269.—Head of tibia, with semilunar cartilages, etc. Seen from above. Right side.

spine of the tibia, to the popliteal notch, and to the posterior extremity of the external semilunar fibrocartilage; and passes upward, forward, and inward, to

be inserted into the outer and fore part of the inner condyle of the femur. It is in relation, in *front*, with the anterior crucial ligament; *behind*, with the capsular ligament.

The **semilunar fibrocartilages** (*menisci*) (Figs. 268 and 269) are two crescentic lamellæ which serve to deepen the surface of the head of the tibia, for articulation with the condyles of the femur. The *circumference* of each cartilage is thick, convex, and attached to the inside of the capsule of the knee; the *inner border*

FIG. 270.—Right knee-joint. Sagittal section through the external condyle of the femur. Mesal half of section, from the lateral side. The knee is slightly flexed; the joint surfaces have been pulled a little apart. (Spalteholz.)

is thin, concave, and free. Their *upper surfaces* are concave, and in relation with the condyles of the femur; their *lower surfaces* are flat, and rest upon the head of the tibia. Each cartilage covers nearly the outer two-thirds of the corresponding articular surface of the tibia, leaving the inner third uncovered; both surfaces are smooth and invested by synovial membrane.

The **internal semilunar fibrocartilage** (*meniscus medialis*) is nearly semicircular in form, a little elongated from before backward, and broader behind than

in front; its *anterior extremity*, thin and pointed, is attached to a depression on the anterior margin of the head of the tibia, in front of the anterior crucial ligament; its *posterior extremity* is attached to the depression behind the spine, between the attachments of the external cartilage and the posterior crucial ligaments.

The **external semilunar fibrocartilage** (*meniscus lateralis*) forms nearly an entire circle, covering a larger portion of the articular surface than the internal one.

FIG. 271.—Right knee-joint, from the lateral surface. The joint cavity and several bursae have been injected with a stiffening medium and then dissected out. (Spalteholz.)

It is grooved on its outer side for the tendon of the Popliteus muscle. Its extremities, at their insertion, are interposed between the two extremities of the internal cartilage; the *anterior extremity* is attached in front of the spine of the tibia to the outer side of, and behind, the anterior crucial ligament, with which it blends; the *posterior extremity* is attached behind the spine of the tibia, in front of the posterior extremity of the internal cartilage. Just before its insertion

posteriorly it gives off a strong fasciculus, the ligament of Wrisberg, which passes obliquely upward and outward, to be inserted into the inner condyle of the femur, close to the attachment of the posterior crucial ligament. Occasionally a small fasciculus is given off which passes forward to be inserted into the back part of the anterior crucial ligament. The external cartilage gives off from its anterior convex margin a fasciculus which forms the transverse ligament.

The **transverse ligament** (*ligamentum transversum genu*) (Fig. 269) is a band of fibres which passes transversely from the anterior convex margin of the external cartilage to the anterior convex margin of the internal cartilage; its thickness varies considerably in different subjects, and it is sometimes absent altogether.

The **coronary ligaments** (*ligamenta coronaria*) are merely portions of the capsular ligament, which connect the circumference of each of the semilunar fibrocartilages with the margin of the head of the tibia.

Synovial Membrane (Figs. 270 and 271).—The synovial membrane encloses the **articular cavity** (*cavum articulare*) of the knee-joint. It is the largest and most extensive synovial membrane in the body. Commencing above the upper border of the patella, it forms, on the lower part of the front of the shaft of the femur, a short *cul-de-sac* beneath the Quadriceps extensor tendon of the thigh; this communicates, by an orifice of variable size, with a synovial bursa interposed between the tendon and the front of the femur (*bursa suprapatellaris*). On each side of the patella the synovial membrane extends beneath the aponeurosis of the Vasti muscles, and more especially beneath that of the Vastus internus. Below the patella it is separated from the anterior ligament by the anterior part of the capsule and a considerable quantity of adipose tissue, known as the **infrapatellar pad** (Fig. 270). In this situation the synovial membrane sends off a triangular prolongation, containing a few ligamentous fibres, which extends from the anterior part of the joint below the patella to the front of the intercondyloid notch. This fold has been termed the **ligamentum mucosum** (*plica synovialis patellaris*). It also sends off two fringe-like folds, called the **ligamenta alaria** (*plicae alares*) (Fig. 270), which extend from the sides of the ligamentum mucosum, upward and laterally between the patella and femur. On either side of the joint it passes downward from the femur, lining the capsule to its point of attachment to the semilunar cartilages; it may then be traced over the upper surfaces of these cartilages to their free borders, and from thence along their under surfaces to the tibia. At the back part of the external one it forms a *cul-de-sac* between the groove on its surface and the tendon of the Popliteus; it surrounds the crucial ligaments and lines the inner surface of the ligaments which enclose the joint. The pouch of synovial membrane between the Quadriceps extensor tendon and the front of the femur is supported, during the movements of the knee, by a small muscle, the Subcrureus, which is inserted into the upper part of the capsular ligament.

The folds of synovial membrane and the fatty processes contained in them act, as it seems, mainly as a padding to fill up interspaces and obviate concussions. Sometimes the bursa beneath the Quadriceps extensor is completely shut off from the rest of the synovial cavity, thus forming a closed sac between the Quadriceps and the lower part of the front of the femur; sometimes it communicates with the synovial cavity by a minute aperture; usually the two cavities are incompletely separated by a synovial fold.

Bursæ.—The bursæ about the knee-joint are the following: In front there are four bursæ; one is interposed between the patella and the skin. It is known as the **prepatellar bursa** (*bursa prepatellaris subcutanea*); another, of small size, between the upper part of the tuberosity of the tibia and the ligamentum patellæ is called the **deep infrapatellar bursa** (*bursa infrapatellaris profunda*); and a third between the lower part of the tuberosity of the tibia and the skin, the **subcutaneous tibial bursa** (*bursa subcutanea tuberositatis tibiae*). A fourth bursa exists in front, the **suprapatellar bursa** (*bursa suprapatellaris*). It lies between the anterior surface of the lower end of the femur and the posterior surface of the Quadriceps femoris. Spalteholz says that the suprapatellar bursa is closely connected with the Quadriceps tendon and is usually incompletely shut off from the cavity of the joint.¹ Occasionally there is a bursa between the expansion of the fascia lata and the Quadriceps and the patella (*bursa prepatellaris subfascialis*), and sometimes one between the tendon of the Quadriceps and the anterior surface of the patella (*bursa prepatellaris subtendinea*). On the outer side there are four bursæ: (1) One (which sometimes communicates with the joint) beneath the outer head of the Gastrocnemius; (2) one above the external lateral ligament between it and the tendon of the Biceps femoris; (3) one beneath the

¹ Spalteholz's Hand Atlas of Human Anatomy. Translated by Lewellys F. Barker.

external lateral ligament between it and the tendon of the Popliteus (this is sometimes only an expansion from the next bursa); (4) one beneath the tendon of the Popliteus (*bursa musculi poplitei*) between it and the condyle of the femur, which is almost always an extension from the synovial membrane of the joint. On the inner side there are *five* bursæ: (1) One beneath the inner head of the Gastrocnemius, which sends a prolongation between the tendons of the Gastrocnemius and Semimembranosus; this bursa often communicates with the joint; (2) one above the internal lateral ligament between it and the tendons of the Sartorius, Gracilis, and Semitendinosus; (3) one beneath the internal lateral ligament between it and the tendon of the Semimembranosus; this is sometimes only an expansion from the next bursa; (4) one beneath the tendon of the Semimembranosus, between it and the head of the tibia; (5) sometimes there is a bursa between the tendons of the Semimembranosus and of the Semitendinosus.

Structures around the Joint.—In *front* and *at the sides*, the Quadriceps extensor; on the *outer side*, the tendons of the Biceps femoris and the Popliteus and the external popliteal nerve; on the *inner side*, the Sartorius, Gracilis, Semitendinosus, and Semimembranosus; *behind*, an expansion from the tendon of the Semimembranosus, the popliteal vessels, and the internal popliteal nerve, the Popliteus, the Plantaris, and the inner and outer heads of the Gastrocnemius, some lymph nodes, and fat.

The **arteries** supplying the joint are derived from the anastomotica magna branch of the femoral, articular branches of the popliteal, anterior and posterior recurrent branches of the anterior tibial, and a descending branch from the external circumflex of the profunda.

The **nerves** are derived from the obturator, femoral, and external and internal popliteal.

Movements.—The knee-joint permits of movements of *flexion* and *extension*, and, in certain positions, of *slight rotation* inward and outward. The movement of flexion and extension does not, however, take place in a simple, finger-like manner, as in other joints, but is a complicated movement, consisting of a certain amount of gliding and rotation; so that the same part of one articular surface is not always applied to the same part of the other articular surface, and the axis of motion is not a fixed one. If the joint is examined while in a condition of extreme flexion, the posterior part of the articular surfaces of the tibia will be found to be in contact with the posterior rounded extremities of the condyles of the femur; and if a simple hinge-like movement were to take place, the axis, around which the revolving movement of the tibia occurs, would be in the back part of the condyle. If the leg is now brought forward into a position of semiflexion, the upper surface of the tibia will be seen to glide over the condyles of the femur, so that the middle part of the articular facets are in contact, and the axis of rotation must therefore have shifted forward to nearer the centre of the condyles. If the leg is now brought into the extended position, a still further gliding takes place and a further shifting forward of the axis of rotation. This is not, however, a simple movement, but is accompanied by a certain amount of rotation outward around a vertical axis drawn through the centre of the head of the tibia. This rotation is due to the greater length of the internal condyle, and to the fact that the anterior portion of its articular surface is inclined obliquely outward. In consequence of this it will be seen that toward the close of the movement of extension—that is to say, just before complete extension is effected—the tibia glides obliquely upward and outward over this oblique surface on the inner condyle, and the leg is therefore necessarily rotated outward. In flexion of the joint the converse of these movements takes place; the tibia glides backward around the end of the femur, and at the commencement of the movement the tibia is directed downward and inward along the oblique curve of the inner condyle, thus causing an inward rotation to the leg.

During flexion and extension the patella moves on the lower end of the femur, but this movement is not a simple gliding one; for if the articular surface of this bone is examined, it will be found to present on each side of the central vertical ridge two less marked transverse ridges, which divide the surface, except a small portion along the inner border, which is cut off by a slight vertical ridge into six facets (Fig. 272), and therefore does not present a uniform curved surface as would be the case if a simple gliding movement took place. These six facets—three on each side of the median vertical ridge—correspond to and denote the parts of the bone, respectively, in contact with the condyles of the femur during flexion, semiflexion, and extension. In flexion only the upper facets on the patella are in contact with the trochlea of the femur; the lower two-thirds of the bone rests upon the mass of fat which occupies the space between the femur and tibia. In the semiflexed position of the joint the middle facets on the patella rest upon the most prominent portion of the trochlea, and thus afford greater leverage to the Quadriceps by increasing its distance from the centre of motion. In complete extension the patella is drawn up, so that only the lower facets are in contact with the trochlea. The narrow strip

FIG. 272.—View of the posterior surface of the patella, showing diagrammatically the areas of contact with the femur in different positions of the knee.

along the inner border is in contact with the outer aspect of the internal condyle when the leg is fully flexed at the knee-joint. As in the elbow, so it is in the knee—the axis of rotation in flexion and extension is not precisely at right angles to the axis of the bone, but during flexion there is a certain amount of alteration of plane; so that, whereas in flexion the femur and tibia are in the same plane, in extension the one bone forms an angle of about 10 degrees with the other. There is, however, this difference between the two extremities: that in the upper, during extension, the humeri are parallel and the bones of the forearm diverge; in the lower, the femora converge below and the tibiae are parallel.

In addition to the slight rotation during flexion and extension, the tibia enjoys an independent rotation on the condyles of the femur in certain positions of the joint. This movement takes place between the articular menisci and the tibia, whereas the movement of flexion and extension takes place between the articular menisci and the femur. So that the knee may be said to consist of two joints, separated by the menisci—an upper, *meniscotemoral*, in which flexion and extension take place; and a lower, *meniscotibial*, allowing of a certain amount of rotation. This latter movement can only take place in the semiflexed position of the limb, when all the ligaments are relaxed.

During *flexion* the ligamentum patellae is put upon the stretch, as is also the posterior crucial ligament in extreme flexion. The other ligaments are all relaxed by flexion of the joint, though the relaxation of the anterior crucial ligament is very trifling. During life flexion is checked by the contact of the leg with the thigh. In the act of extending the leg upon the thigh the ligamentum patellae is tightened by the Quadriceps extensor; but when the leg is fully extended, as in the erect posture, the ligament becomes relaxed, so as to allow free lateral movement to the patella, which then rests on the front of the lower end of the femur. The other ligaments, with the exception of the posterior crucial, which is partly relaxed, are all on the stretch. When the limb has been brought into a straight line, extension is checked mainly by the tension of all the ligaments except the posterior crucial and the ligamentum patellae. The movements of *rotation* of which the knee is capable are permitted in the semiflexed condition by the partial relaxation of both crucial ligaments, as well as of the lateral ligaments. Rotation inward appears to be limited by the tension of the anterior crucial ligament, and by the interlocking of the two ligaments; but rotation outward does not appear to be checked by either crucial ligament, since they uncross during the execution of this movement, but it is checked by the lateral ligaments, especially the internal. The main function of the crucial ligaments is to act as a direct bond of union between the tibia and femur, preventing the former bone from being carried too far backward or forward. Thus, the anterior crucial ligament prevents the tibia being carried too far forward by the Extensor tendons, and the posterior crucial checks too great movement backward by the Flexors. They also assist the lateral ligaments in resisting any lateral bending of the joint. The semilunar cartilages are intended, evidently, to adapt to a certain extent the surface of the tibia to the shape of the femur, in order to fill intervals which would otherwise occur in the changing of joint position and to interrupt jars which otherwise would be so frequently transmitted up the limb through jumping or falling on the feet. These cartilages also contribute to the varieties of motion—flexion, extension, and rotation—as explained above. The patella is a great defence to the knee-joint from any injury inflicted in front, and it distributes upon a large and tolerably even surface during kneeling the pressure which would otherwise fall upon the prominent ridges of the condyles; it also affords leverage to the Quadriceps extensor muscle when it acts upon the tibia; and Mr. Ward has pointed out¹ how this leverage varies in the various positions of the joint, so that the action of the muscles produces velocity at the expense of force in the commencement of extension, and, on the contrary, at the close of extension tends to diminish velocity, and therefore the shock to the ligaments at the moment tension of the structures takes place.

Extension of the leg on the thigh is performed by the Quadriceps extensor; *flexion* by the Hamstring muscles, assisted by the Gracilis and Sartorius, and, indirectly, by the Gastrocnemius, Popliteus, and Plantaris; *rotation outward*, by the Biceps femoris; and *rotation inward* by the Popliteus, Semitendinosus, and, to a slight extent, the Semimembranosus, the Sartorius, and the Gracilis.

Surface Form.—The interval between the two bones entering into the formation of the knee-joint can always easily be felt. If the limb is extended, it is situated on a slightly higher level than the apex of the patella; but if the limb is slightly flexed, a knife carried horizontally backward immediately below the apex of the patella would pass directly into the joint. When the knee-joint is distended with fluid, the outline of the synovial membrane at the front of the knee may be fairly well mapped out.

Applied Anatomy.—The *bursae* about the knee are frequently the seat of inflammation. Enlargement of the *prepatellar bursa* constitutes *housemaid's knee*. The bursa beneath the

¹ Human Osteology, p. 405.

Semimembranosus may enlarge greatly. It communicates with the knee-joint and can frequently be made to disappear by pressure when the knee is flexed. Treves points out that enlargement of the bursa between the Biceps tendon and the external lateral ligament causes great pain because the peroneal nerve crosses the sac.¹

From a consideration of the construction of the knee-joint it would at first sight appear to be one of the least secure of any of the joints in the body. It is formed between the two longest bones, and therefore the amount of leverage which can be brought to bear upon it is very considerable; the articular surfaces are but ill adapted to each other, and the range and variety of motion which it enjoys is great. All these circumstances tend to render the articulation very insecure; but, nevertheless, on account of the very powerful ligaments which bind the bones together, the joint is one of the strongest in the body, and *dislocation from traumatism* is of very rare occurrence. When, on the other hand, the ligaments have been softened or destroyed by disease, *partial displacement* is very liable to occur, and is frequently brought about by the mere action of the muscles displacing the articular surfaces from each other. The tibia may be dislocated in any direction from the femur—forward, backward, inward, or outward; or a combination of two of these dislocations may occur—that is, the tibia may be dislocated forward and laterally, or backward and laterally, and any of these dislocations may be complete or incomplete. As a rule, however, the antero-posterior dislocations are complete, the lateral ones incomplete.

One or other of the *semilunar cartilages* may become displaced and nipped between the femur and tibia. The accident is produced by a twist of the leg when the knee is flexed, and is accompanied by a sudden pain and fixation of the knee in a flexed position. The cartilage may be displaced either inward or outward; that is to say, either inward toward the tibial spine, so that the cartilage becomes lodged in the intercondyloid notch; or outward, so that the cartilage projects beyond the margin of the articular surface. *Acute synovitis*, the result of traumatism or exposure to cold, is very common in the knee, on account of its superficial position. When distended with fluid, the swelling shows itself above and at the sides of the patella, reaching about an inch or more above the trochlear surface of the femur, and extending a little higher under the Vastus internus than the Vastus externus. Occasionally the swelling may extend two inches or more. At the sides of the patella the swelling extends lower at the inner side than it does on the outer side. The lower level of the synovial membrane is just above the level of the upper part of the head of the fibula. In the middle line it covers the upper third of the ligamentum patellae, being separated from it, however, by the capsule and a pad of fat. *Chronic synovitis* principally shows itself in the form of pulpy degeneration of the synovial membrane, the result of *tuberculous arthritis*. The reasons why tuberculous disease of the knee so often commences in the synovial membrane appear to be the complex and extensive nature of this sac; the extensive vascular supply to it; and the fact that injuries are generally diffused and applied to the front of the joint rather than to the ends of the bone. *Syphilis* not infrequently attacks the knee-joint. In the hereditary form of the disease the attack is usually symmetrical—both joints are involved. They become filled with synovial effusion and cure is very difficult. In acquired syphilis gummatous infiltration of the synovial membrane may take place. The knee is one of the joints most commonly affected with *osteoarthritis*, and is said to be more frequently the seat of this disease in women than in men. The occurrence of the so-called *loose cartilage* is almost confined to the knee, though loose cartilages are occasionally met with in the elbow, and, rarely, in some other joints. Many of them occur in cases of *osteoarthritis*, in which calcareous or cartilaginous material is formed in one of the synovial fringes and constitutes the foreign body, and may or may not become detached, in the former case only meriting the usual term, "loose" cartilage. In other cases they have their origin in the exudation of inflammatory lymph, and possibly, in some rare instances, a portion of the articular cartilage or one of the semilunar cartilages becomes detached and constitutes the foreign body.

Genu valgum, or *knock-knee*, is a common deformity of childhood, in which, owing to changes in and about the joint, the angle between the outer border of the tibia and femur is diminished, so that as the patient stands the two internal condyles of the femora are in contact, but the two internal malleoli of the tibiae are more or less widely separated from each other. When, however, the knees are flexed to a right angle, the two legs are practically parallel with each other. At the commencement of the disease there is a yielding of the internal lateral ligament and other fibrous structures on the inner side of the joint; as a result of this there is a constant undue pressure of the outer tuberosity of the tibia against the outer condyle of the femur. This extra pressure causes arrest of growth, and, possibly, wasting of the outer condyle, and a consequent tendency for the tibia to become separated from the internal condyle. To prevent this the internal condyle becomes depressed; probably, as was first pointed out by Mikulicz, by an increased growth of the lower end of the diaphysis on its inner side, so that the line of the epiphysis becomes oblique instead of transverse to the axis of the bone, with a direction down-

¹ Applied Anatomy.

ward and inward. It is often said that the deformity is produced by undue length of the inner condyle, but in reality the condyle grows as the deformity progresses.

Excision of the knee-joint is most frequently required for tuberculous disease of this articulation, but is also practised in cases of disorganization of the knee after rheumatic fever, pyemia, etc., in osteoarthritis, and in ankylosis. It is also occasionally called for in cases of injury, gunshot or otherwise. The operation is best performed either by a horseshoe incision, starting from one condyle, descending as low as the tubercle of the tibia, where it crosses the leg, and is then

carried upward to the other condyle; or by a transverse incision across the patella. In this latter incision the patella is either removed or sawed across, and the halves subsequently sutured together. The bones having been cleared, and in those cases where the operation is performed for tuberculous disease all pulpy tissue having been carefully removed, the section of the femur is first made. This should never include, in children, more than, at the most, two-thirds of the articular surface, otherwise the epiphyseal cartilage will be involved, with disastrous results as regards the growth of the limb. Afterward a thin slice should be removed from the upper end of the tibia, not more than half an inch. If any diseased tissue still appears to be left in the bones, it should be removed with the gouge rather than by making a further section of the bones.

FIG. 273.—Ligaments of the right leg, from in front. (Spalteholz.)

III. The Tibiofibular Articulation (Articulatio Tibiofibularis).

The articulations between the tibia and fibula are effected by ligaments which connect both extremities, as well as the shafts of the bones. It may, consequently, be subdivided into three articulations: (1) The **superior tibiofibular articulation**. (2) The **middle tibiofibular ligament or interosseous membrane**. (3) The **inferior tibiofibular articulation**.

1. THE SUPERIOR TIBIOFIBULAR ARTICULATION (ARTICULATIO TIBIOFIBULARIS).

This articulation is an arthrodial joint. The contiguous surfaces of the bones present two flat, oval facets covered with cartilage, and are interconnected by the following ligaments:

Capsular.

Anterior Superior Tibiofibular.

Posterior Superior Tibiofibular.

The **capsular ligament** (*capsula articularis*) consists of a membranous bag which surrounds the articulation, being attached around the margins of the articular facets on the tibia and fibula, and is much thicker in front than behind.

The **anterior superior ligament** (Fig. 273) consists of two or three broad and flat bands which pass obliquely upward and inward from the front of the head of the fibula to the front of the outer tuberosity of the tibia.

The **posterior superior ligament** (Fig. 266) is a single thick and broad band which passes upward and inward from the back part of the head of the fibula to the back part of the outer tuberosity of the tibia. It is covered by the tendon of the Popliteus muscle.

Synovial Membrane.—A synovial membrane lines this articulation, which at its upper and back part is occasionally continuous with that of the knee-joint.

2. THE MIDDLE TIBIOFIBULAR LIGAMENT OR INTEROSSEOUS MEMBRANE (MEMBRANA INTEROSSEA CRURIS) (Fig. 273).

An **interosseous membrane** extends between the contiguous margins of the tibia and fibula and separates the muscles on the front from those on the back of the leg. It consists of a thin, aponeurotic lamina composed of oblique fibres which for the most part pass downward and outward between the interosseous ridges on the two bones; some few fibres, however, pass in the opposite direction, downward and inward. It is broader above than below. Its upper margin does not quite reach the superior tibiofibular joint, but presents a free concave border, above which is a large, oval aperture for the passage of the anterior tibial vessels forward to the anterior aspect of the leg. At its lower part is an opening for the passage of the anterior peroneal vessels. It is continuous below with the inferior interosseous ligament, and is perforated in numerous places for the passage of small vessels. It is in relation, in *front*, with the Tibialis anticus, Extensor longus digitorum, Extensor proprius hallucis, Peroneus tertius, and the anterior tibial vessels and nerve; *behind*, with the Tibialis posticus and Flexor longus hallucis.

3. THE INFERIOR TIBIOFIBULAR ARTICULATION (SYNDESMOSIS TIBIOFIBULARIS) (Figs. 275, 276).

This articulation is formed by the rough, convex surface of the inner side of the lower end of the fibula, connected with a concave rough surface on the outer side of the tibia. Below, to the extent of about one-sixth of an inch, these surfaces are smooth, and covered with cartilage, which is continuous with that of the ankle-joint. The ligaments of this joint are:

Anterior Inferior Tibiofibular.
Posterior Inferior Tibiofibular.

Transverse or Inferior.
Inferior Interosseous.

The **anterior inferior ligament** (*ligamentum malleoli lateralis anterioris*) (Figs. 273 and 277) is a flat, triangular band of fibres, broader below than above, which extends obliquely downward and outward, between the adjacent margins of the tibia and fibula, on the front aspect of the articulation. It is in relation, in *front*, with the Peroneus tertius, the aponeurosis of the leg, and the integument, *behind*, with the inferior interosseous ligament; and lies in contact with the cartilage covering the astragalus.

The **posterior inferior ligament** (*ligamentum malleoli lateralis posterius*) (Fig. 277), smaller than the preceding, is disposed in a similar manner on the posterior surface of the articulation.

The **inferior transverse ligament** lies under cover of the posterior ligament, and is a strong, thick band of yellowish fibres which passes transversely across the back of the joint, from the external malleolus to the posterior border of the articular surface of the tibia, almost as far as its malleolar process. This ligament projects below the margin of the bones, and forms part of the articulating surface for the astragalus.

The **inferior interosseous ligament** (Fig. 275) consists of numerous short, strong, fibrous bands which pass between the contiguous rough surfaces of the tibia and fibula, and constitute the chief bond of union between the bones. This ligament is continuous above with the interosseous membrane.

Synovial Membrane.—The synovial membrane lining the articular surface is derived from that of the ankle-joint (Fig. 275).

Movements.—The movement permitted in these articulations is limited to a very slight gliding of the articular surfaces one upon another.

IV. The Tibiotarsal Articulation, or Ankle-joint (*Articulatio Talocruralis*) (Figs. 274, 275).

The ankle is a ginglymus or hinge-joint. The bones entering into its formation are the lower extremity of the tibia and its malleolus and the external malleolus of the fibula, which forms a mortise (Fig. 273) to receive the upper convex surface

FIG. 274.—Ankle-joint: tarsal and tarsometatarsal articulations. Internal view. Right side.

of the astragalus and its two lateral facets. The bony surfaces are covered by hyaline cartilage and interconnected by a **capsule** (*capsula articularis*), which in places forms thickened bands constituting the following ligaments:

Anterior.
Posterior.

Internal Lateral.
External Lateral.

The **anterior tibiotalar ligament** (*ligamentum talotibiale anterius*) is a broad, thin, membranous layer, attached, *above*, to the anterior margin of the lower extremity of the tibia; *below*, to the margin of the astragalus, in front of its articular surface. It is in relation, in *front*, with the Extensor tendons of the toes, with the tendons of the Tibialis anticus and Peroneus tertius, and the anterior tibial vessels and nerve; *behind*, it lies in contact with the synovial membrane.

The **posterior tibiotalar ligament** (*ligamentum talotibiale posterius*) is very thin, and consists principally of transverse fibres. It is attached, *above*, to the margin of the articular surface of the tibia, blending with the transverse tibio-fibular ligament; *below*, to the astragalus, behind its superior articular facet. *Externally*, where a somewhat thickened band of transverse fibres is attached to the hollow on the inner surface of the external malleolus, it is thicker than internally.

FIG. 275.—Frontal section through the ankle-joint and the calcaneo-astragaloid articulation. (Poirier and Charpy.)

The **internal lateral or deltoid ligament** (*ligamentum calcaneotibiale*) (Figs. 275 and 276) consists of a superficial and a deep set of fibres; the **superficial set** constitute a strong, flat, triangular band, which is attached, *above*, to the apex and to the anterior and posterior borders of the inner malleolus. The most *anterior* fibres pass forward to be inserted into the scaphoid bone and the inferior calcaneoscaphoid ligament; the *middle* descend almost perpendicularly to be inserted into the sustentaculum tali of the os calcis; and the *posterior* fibres pass backward and outward to be attached to the inner side of the astragalus. The **deep set** is attached, *above*, to the notch of the inner malleolus, and, *below*, to the inner side of the astragalus. This ligament is covered by the tendons of the Tibialis posticus and Flexor longus digitorum muscles.

The **external lateral ligament** (*ligamenta talofibularia et calcaneofibulare*) (Figs. 276 and 277) consists of three distinctly specialized fasciculi of the capsule, taking different directions and separated by distinct intervals; for which reason it is divided by some anatomists into three distinct ligaments, and so described.¹

¹ Humphry. On the Skeleton, p. 559.

The **anterior fasciculus** (*ligamentum talofibulare anterius*), the shortest of the three, passes from the anterior margin of the external malleolus forward and inward to the astragalus, in front of its external articular facet.

FIG. 276.—Joints of the right foot, from the back of the foot. (Spalteholz.)

The **posterior fasciculus** (*ligamentum talofibulare posterius*), the most deeply seated, passes inward from the depression at the inner and back part of the external malleolus to a prominent tubercle on the posterior surface of the astragalus. Its fibres are almost horizontal in direction.

The **middle fasciculus** (*ligamentum calcaneofibulare*) (Figs. 276 and 277), the longest of the three, is a narrow, rounded cord passing from the apex of the

external malleolus downward and slightly backward to a tubercle on the outer surface of the os calcis. It is covered by the tendons of the Peroneus longus and brevis.

Synovial Membrane.—The synovial membrane (Fig. 275) invests the inner surface of the ligaments, and sends a duplicature upward between the lower extremities of the tibia and fibula for a short distance.

Relations.—The tendons, vessels, and nerves in connection with the joint are, in *front*, from within outward, the Tibialis anticus, Extensor proprius hallucis, anterior tibial vessels and nerve, Extensor longus digitorum, and Peroneus tertius; *behind*, from within outward, the Tibialis posticus, Flexor longus digitorum, posterior tibial vessels and nerve, Flexor longus hallucis; and in the groove behind the external malleolus, the tendons of the Peroneus longus and brevis.

The **arteries** supplying the joint are derived from the malleolar branches of the anterior tibial and the peroneal.

The **nerves** are derived from the anterior and posterior tibial.

FIG. 277.—Ankle-joint: tarsal and tarsometatarsal articulations. External view. Right side.

Movements.—The movements of the joint are those of *flexion* and *extension*. *Flexion* consists in the approximation of the dorsum of the foot to the front of the leg, while in *extension* the heel is drawn up and the toes pointed downward. The malleoli tightly embrace the astragalus in all positions of the joint, so that any slight degree of lateral movement which may exist is simply due to stretching of the inferior tibiofibular ligaments and slight bending of the shaft of the fibula. Of the ligaments, the internal is of very great strength—so much so that it usually resists a force which fractures the process of bone to which it is attached. Its middle portion, together with the middle fasciculus of the external lateral ligament, binds the bones of the leg firmly to the foot and resists displacement in every direction. Its anterior and posterior fibres limit extension and flexion of the foot, respectively, and the anterior fibres also limit abduction. The posterior portion of the external lateral ligament assists the middle portion in resisting the displacement of the foot backward, and deepens the cavity for the reception of the astragalus. The anterior fasciculus is a security against the displacement of the foot forward, and limits extension of the joint. The movements of *inversion* and *eversion* of the foot, together with the minute changes in form by which it is applied to the ground or takes hold of an object in climbing, etc., are mainly effected in the tarsal joints, the one which enjoys the greatest amount of motion being that between the astragalus and os calcis behind and the scaphoid and cuboid in front. This is often called the **transverse** or **mediotarsal joint**, and it can, with the subordinate joints of the tarsus, replace the ankle-joint in a great measure when the latter has become ankylosed.

Extension of the tarsal bones upon the tibia and fibula is produced by the *Gastrocnemius*, *Soleus*, *Plantaris*, *Tibialis posticus*, *Peroneus longus* and *brevis*, *Flexor longus digitorum*, and *Flexor longus hallucis*; *flexion*, by the *Tibialis anticus*, *Peroneus tertius*, *Extensor longus digitorum*, and *Extensor proprius hallucis*¹ (Fig. 269); *inversion*, in the extended position, is produced by the *Tibialis anticus* and *posticus*; and *eversion* by the *Peronei*.

Surface Form.—The line of the ankle-joint may be indicated by a transverse line drawn across the front of the lower part of the leg, about half an inch above the level of the tip of the internal malleolus.

Applied Anatomy.—Displacement of the trochlear surface of the astragalus from the tibio-fibular mortise is not of common occurrence, as the ankle-joint is a very strong and powerful articulation, and great force is required to produce dislocation. Nevertheless, dislocation does occasionally occur, both in antero-posterior and a lateral direction. In the latter, which is the most common, fracture is a necessary accompaniment of the injury. The dislocation in these cases is somewhat peculiar, and is not a displacement in a horizontally lateral direction, such as usually occurs in lateral dislocations of ginglymoid joints, but the astragalus undergoes a partial rotation around an antero-posterior axis drawn through its own centre, so that the superior surface, instead of being directed upward, is inclined more or less inward or outward according to the variety of the displacement.

FIG. 278.—Section of the right foot near its inner border, dividing the tibia, astragalus, calcaneus, scaphoid, internal cuneiform, and first metatarsal bone, and the first phalanx of the great toe. (After Braune.)

The ankle-joint is more frequently sprained than any joint in the body, and this may lead to *acute synovitis*. In these cases, when the synovial sac is distended with fluid, the bulging appears principally in the front of the joint, beneath the anterior tendons, and on either side, between the *Tibialis anticus* and the internal lateral ligament on the inner side, and between the *Peroneus tertius* and the external lateral ligament on the outer side. In addition to this, bulging frequently occurs posteriorly, and a fluctuating swelling may be detected on either side of the *tendo Achillis*.

Chronic synovitis may result from frequent sprains, and when once this joint has been sprained it is more liable to a recurrence of the injury than it was before; chronic synovitis may be tuberculous in its origin, the disease usually commencing in the astragalus and extending to the joint, though it may commence as a synovitis, the result probably of some slight strain in a tuberculous subject.

Excision of the ankle-joint is not often performed for two reasons. In the first place, disease of the articulation, for which this operation is indicated, is frequently associated with disease of the tarsal bones, which prevents its performance; and, secondly, the foot after excision is frequently of very little use; far less, in fact, than after a Syme's amputation, which is often, therefore, a preferable operation in these cases.

¹ The student must bear in mind that the *Extensor longus digitorum* and *Extensor proprius hallucis* are *extensors* of the toes, but *flexors* of the ankle, and that the *Flexor longus digitorum* and *Flexor longus hallucis* are *flexors* of the toes, but *extensors* of the ankle.

V. The Articulations of the Tarsus (*Articulationes Intertarseae*) (Figs. 276, 277).

1. THE ARTICULATION OF THE OS CALCIS AND ASTRAGALUS, OR THE CALCaneo-ASTRAGALOID ARTICULATION (*ARTICULATIO TALOCALCANEAE*) (Fig. 276).

The articulations between the os calcis and astragalus are two in number—*anterior* and *posterior*. They are *arthrodial* joints. The bones are connected by a **capsule** (*capsula articularis*), which is at certain points accentuated into definite ligaments. There are five ligaments in this articulation:

External Calcaneo-astragaloid.	Anterior Calcaneo-astragaloid.
Internal Calcaneo-astragaloid.	Posterior Calcaneo-astragaloid.
Interosseous.	

The **external calcaneo-astragaloid ligament** (*ligamentum talocalcaneum laterale*) (Fig. 277) is a short, strong, fasciculus passing from the outer surface of the astragalus, immediately beneath its external malleolar facet, to the outer surface of the os calcis. It is placed in front of the middle fasciculus of the external lateral ligament of the ankle-joint, with the fibres of which it is parallel.

The **internal calcaneo-astragaloid ligament** (*ligamentum talocalcaneum mediale*) is a band of fibres connecting the internal tubercle of the back of the astragalus with the back of the sustentaculum tali. Its fibres blend with those of the inferior calcaneoscaphoid ligament.

The **anterior calcaneo-astragaloid ligament** (*ligamentum talocalcaneum anteriorius*) passes from the front and outer surface of the neck of the astragalus to the superior surface of the os calcis.

The **posterior calcaneo-astragaloid ligament** (*ligamentum talocalcaneum posteriorius*) connects the external tubercle of the astragalus with the upper and inner part of the os calcis; it is a short band, the fibres of which radiate from their narrow attachment to the astragalus.

The **interosseous ligament** (*ligamentum talocalcaneum interosseum*) (Fig. 280) forms the chief bond of union between the bones. It consists of numerous vertical and oblique fibres attached by one extremity to the groove between the articulating facets on the under surface of the astragalus; by the other to a corresponding depression on the upper surface of the os calcis. It is very thick and strong, being at least an inch in breadth from side to side, and serves to unite the os calcis and astragalus solidly together.

Synovial Membrane.—The synovial membranes (Fig. 280) are *two* in number, one for the posterior calcaneo-astragaloid articulation, a second for the anterior calcaneo-astragaloid joint. The latter synovial membrane is continued forward between the contiguous surfaces of the astragalus and scaphoid bones.

Movements.—The movements permitted between the astragalus and os calcis are limited to a *gliding* of the one bone on the other in a direction from before backward, and from side to side.

2. THE ARTICULATION OF THE OS CALCIS WITH THE CUBOID (*ARTICULATIO CALCANEOCUBOIDEA*) (Fig. 276).

In this joint the articular capsule (*capsula articularis*) is strengthened at certain points by definite ligaments.

The ligaments connecting the os calcis with the cuboid are four in number:

Superior or Dorsal Calcaneocuboid.	Two Plantar {	Long Calcaneocuboid.
The Internal Calcaneocuboid.		Short Calcaneocuboid.

The **superior calcaneocuboid ligament** (*ligamentum calcaneocuboideum dorsale*) (Fig. 277) is a broad portion of the capsule which passes between the contiguous surfaces of the os calcis and cuboid on the dorsal surface of the joint.

The **internal calcaneocuboid** or the **interosseous ligament** (*pars calcaneocuboidea ligamenti bifurcati*) is a short but thick and strong band of fibres arising from the os calcis, in the deep hollow which intervenes between it and the astragalus, and closely blended, at its origin, with the superior calcaneoscaphoid ligament. These two ligaments are often regarded as a single bifurcated ligament (*ligamentum bifurcatum*). The internal calcaneocuboid ligament is inserted into the inner side of the cuboid bone. This ligament forms one of the chief bonds of union between the first and second rows of the tarsus.

The **long calcaneocuboid** or **long plantar** or **superficial long plantar ligament** (*ligamentum plantare longum*) (Fig. 279), the more superficial of the two plantar ligaments, is the longest of all the ligaments of the tarsus; it is attached to the under surface of the os calcis, from near the tuberosities, as far forward as the anterior tubercle; its fibres pass forward to be attached to the ridge on the under surface of the cuboid bone, the more superficial fibres being continued onward to the bases of the second, third, and fourth metatarsal bones. This ligament crosses the groove on the under surface of the cuboid bone, converting it into a canal for the passage of the tendon of the Peroneus longus.

The **short calcaneocuboid** or **short plantar ligament** (*ligamentum calcaneocuboideum plantare*) (Fig. 279) lies nearer the bones than the preceding, from which it is separated by a little areolar tissue. It is exceedingly broad, about an inch in length, and extends from the tubercle and the depression in front of it, on the fore part of the under surface of the os calcis, to the inferior surface of the cuboid bone behind the peroneal groove.

Synovial Membrane (Fig. 280).—The synovial membrane in this joint is distinct. It lines the inner surface of the ligaments.

Movements.—The movements permitted between the os calcis and cuboid are limited to a slight *gliding* upon each other.

3. THE LIGAMENTS CONNECTING THE OS CALCIS AND SCAPHOID.

Though these two bones do not, as a rule, directly articulate, they are connected by two ligaments:

Superior or External Calcaneoscaphoid.
Inferior or Internal Calcaneoscaphoid.

The **superior or external calcaneoscaphoid** or **calcaneonavicular ligament** (*pars calcaneonavicularis ligamenti bifurcati*) arises, as already mentioned, with the internal calcaneocuboid in the deep hollow between the astragalus and os calcis, constituting a part of the *ligamentum bifurcatum*; it passes forward from the upper surface of the anterior extremity of the os calcis to the outer side of the scaphoid bone. These two ligaments resemble the letter Y, being blended together behind, but separated in front.

The **inferior or internal calcaneoscaphoid** or **calcaneonavicular ligament** (*ligamentum calcaneonaviculare plantare*) (Fig. 279) is by far the larger and stronger of the two ligaments between these bones; it is a broad and thick band of fibres, which passes forward and inward from the anterior margin of the sustentaculum tali of the os calcis to the under surface of the scaphoid bone. This ligament not only serves to connect the os calcis and scaphoid, but supports the head of the astragalus, forming part of the articular cavity in which it is received. The *upper surface* presents a fibrocartilaginous facet, lined with the synovial membrane

continued from the anterior calcaneo-astragaloid articulation, upon which a portion of the head of the astragalus rests. Its *under surface* is in contact with the tendon of the Tibialis posticus muscle, its *inner border* is blended with the fore part of the deltoid ligament, thus completing the socket for the head of the astragalus.

Applied Anatomy.—The inferior calcaneoscaphoid ligament, by supporting the head of the astragalus, is principally concerned in maintaining the arch of the foot, and when it yields the head of the astragalus is pressed downward, inward, and forward by the weight of the body, and the foot become flattened, expanded, and turned outward, constituting the condition known as *flat-foot*. This ligament contains a considerable amount of elastic tissue, so as to give elasticity to the arch and spring to the foot; hence, it is sometimes called the “spring” ligament. It is supported, on its under surface, by the tendon of the Tibialis posticus, which spreads out at its insertion into a number of fasciculi which are attached to most of the tarsal and metatarsal bones; this prevents undue stretching of the ligament, and is a protection against the occurrence of flat-foot.

4. THE ARTICULATION OF THE ASTRAGALUS WITH THE SCAPHOID BONE (ARTICULATIO TALONAVICULARIS) (Fig. 276).

This is an arthrodial joint, the rounded head of the astragalus being received into the concavity formed by the posterior surface of the scaphoid, the anterior articulating surface of the calcaneum, and the upper surface of the inferior calcaneoscaphoid ligament, which fills up the triangular interval between these bones. The only ligament of this joint is the **superior astragaloscaphoid** (Fig. 274). It is a broad band, which passes obliquely forward from the neck of the astragalus to the superior surface of the scaphoid bone. It is thin, and weak in texture, and covered by the Extensor tendons. The inferior calcaneoscaphoid ligament supplies the place of an inferior astragaloscaphoid ligament.

Synovial Membrane (Fig. 280).—The synovial membrane which lines the joint is continued forward from the anterior calcaneo-astragaloid articulation.

Movements.—This articulation permits of considerable mobility, but its feebleness is such as to allow occasionally of dislocation of the other bones of the tarsus from the astragalus.

The **transverse tarsal** or **midtarsal joint** (*articulatio tarsi transversa* [Chopart]) (Figs. 276 and 281) is formed by the articulation of the os calcis with the cuboid, and by the articulation of the astragalus with the scaphoid. The movement which takes place in this joint is more extensive than that in the other tarsal joints, and consists of a sort of rotation by means of which the sole of the foot may be slightly flexed and extended or carried inward (*inverted*) and outward (*everted*).

5. THE ARTICULATION OF THE SCAPHOID WITH THE CUNEIFORM BONES (ARTICULATIO CUNEONAVICULARIS) (Fig. 276).

The scaphoid is connected to the three cuneiform bones by

Dorsal and Plantar Ligaments.

FIG. 279.—Ligaments of the plantar surface of the foot.

The **dorsal ligaments** (*ligamenta navicularicuneiformia dorsalia*) (Figs. 274 and 276) are small, longitudinal bands of fibrous tissue arranged as three bundles, one to each of the cuneiform bones. That bundle of fibres which connects the scaphoid with the internal cuneiform is continued around the inner side of the articulation to be continuous with the plantar ligament which connects these two bones.

The **plantar ligaments** (*ligamenta navicularicuneiformia plantaria*) (Fig. 279) have a similar arrangement to those on the dorsum. They are strengthened by processes given off from the tendon of the Tibialis posticus.

Synovial Membrane (Fig. 280).—The synovial membrane of these joints is part of the great tarsal synovial membrane.

Movements.—The movements permitted between the scaphoid and cuneiform bones are limited to a slight *gliding* upon each other.

6. THE ARTICULATION OF THE SCAPHOID WITH THE CUBOID (ARTICULATIO CUBONAVICULARIS).

The scaphoid bone is connected with the cuboid by

Dorsal, Plantar, and Interosseous Ligaments.

The **dorsal ligament** (*ligamentum cuboideonaviculare dorsale*) (Fig. 277) consists of a band of fibrous tissue which passes obliquely forward and outward from the scaphoid to the cuboid bone.

The **plantar ligament** (*ligamentum cuboideonaviculare plantare*) consists of a band of fibrous tissue which passes nearly transversely between these two bones.

The **interosseous ligament** (Figs. 276 and 280) consists of strong transverse fibres which pass between the rough nonarticular portions of the lateral surfaces of these two bones.

Synovial Membrane (Fig. 280).—The synovial membrane of this joint is part of the great tarsal synovial membrane.

Movements.—The movements permitted between the scaphoid and cuboid bones are limited to a slight *gliding* upon each other.

7. THE ARTICULATIONS OF THE CUNEIFORM BONES WITH EACH OTHER OR THE INTERCUNEIFORM ARTICULATIONS (Fig. 276).

These bones are connected by

Dorsal, Plantar, and Interosseous Ligaments.

The **dorsal ligaments** (*ligamenta intercuneiformia dorsalia*) consist of two bands of fibrous tissue which pass transversely, one connecting the internal with the middle cuneiform, and the other connecting the middle with the external cuneiform.

The **plantar ligaments** (*ligamenta intercuneiformia plantaria*) have a similar arrangement to those on the dorsum. They are strengthened by the processes given off from the tendon of the Tibialis posticus.

The **interosseous ligaments** (*ligamenta intercuneiformia interossea*) consist of strong transverse fibres which pass between the rough nonarticular portions of the lateral surfaces of the first and second and the second and third cuneiform bones. The outer portion of the third cuneiform is attached to the cuboid by the *ligamentum cuneocuboideum interosseum*.

Synovial Membrane (Fig. 280).—The synovial membrane of these joints is part of the great tarsal synovial membrane.

Movements.—The movements permitted between the cuneiform bones are limited to a slight *gliding* upon each other.

8. THE ARTICULATION OF THE EXTERNAL CUNEIFORM BONE WITH THE CUBOID (Fig. 276).

These bones are connected by

Dorsal, Plantar, and Interosseous Ligaments.

The **dorsal ligament** (*ligamentum cuneocuboideum dorsale*) (Fig. 277) consists of a band of fibrous tissue which passes transversely between these two bones.

The **plantar ligament** (*ligamentum cuneocuboideum plantare*) has a similar arrangement. It is strengthened by a process given off from the tendon of the *Tibialis posticus*.

The **interosseous ligament** (*ligamentum cuneocuboideum interosseum*) (Fig. 276) consists of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces of the adjacent sides of these two bones.

Synovial Membrane (Fig. 280).—The synovial membrane of this joint is part of the great tarsal synovial membrane.

Movements.—The movements permitted between the external cuneiform and cuboid are limited to a slight *gliding* upon each other.

Nerve Supply.—All the joints of the tarsus are supplied by the anterior tibial nerve.

Applied Anatomy.—In spite of the great strength of the ligaments which hold the tarsal bones together, *dislocation* at some of the tarsal joints occasionally occurs; these bones, on account of their spongy character, are, as the result of direct violence, more frequently broken than dislocated. When dislocation does occur, it is most commonly in connection with the astragalus; for not only may this bone be dislocated from the tibia and fibula at the ankle-joint, but the other bones may be dislocated from it, the trochlear surface of the bone remaining *in situ* in the tibiofibular mortise. This constitutes what is known as the *subastragaloid dislocation*. Or, again, the astragalus may be dislocated from all its connections—from the tibia and fibula above, the os calcis below, and the scaphoid in front—and may even undergo a rotation, either on a vertical or horizontal axis. In the former case the long axis of the bone becoming directed across the joint, so that the head faces the articular surface on one or other malleolus; or, in the latter, the lateral surfaces becoming directed upward and downward, so that the trochlear surface faces to one or the other side. Finally, dislocation may occur at the mediotarsal joint, the anterior tarsal bones being luxated from the astragalus and calcaneum. The other tarsal bones are also, occasionally, though rarely, dislocated from their connections.

Pes planus, *flat-foot*, or *spay-foot* is a condition in which there is abduction, eversion, and loss of both the longitudinal and the transverse arch. The head of the astragalus passes downward and inward; the anterior portion of the foot is turned outward and the inner side of the foot is lengthened and broadened. Deformity is increased when standing. In severe cases the patient walks on the inner side of the foot. The condition is due to weakness of the *Tibialis posticus* muscle, with a consequent yielding of the tarsal ligaments. Abduction is permitted by yielding of the internal lateral and calcaneo-astragaloid ligaments. Yielding of the calcaneo-scaphoid ligament permits the head of the astragalus to pass downward and forward, and the entire arch falls.

VI. The Tarsometatarsal Articulations (*Articulationes Tarsometatarsee* [Lisfranci]) (Figs. 276, 277).

These are arthrodial joints. The bones entering into their formation are four tarsal bones—viz., the internal, middle, and external cuneiform and the cuboid—which articulate with the metatarsal bones of the five toes. The metatarsal bone of the great toe articulates with the internal cuneiform; that of the second is deeply wedged in between the internal and external cuneiform, rests against the middle cuneiform, and is the most strongly articulated of all the metatarsal

bones; the third metatarsal articulates with the extremity of the external cuneiform; the fourth, with the cuboid and external cuneiform; and the fifth, with the cuboid. The articular surfaces are covered by hyaline cartilage, lined with synovial membrane, and interconnected by capsules and by the following ligaments:

Dorsal.

Plantar.

Interosseous.

The **dorsal ligaments** (*ligamenta tarsometatarsea dorsalia*) consist of strong, flat, fibrous bands, which connect the tarsal with the metatarsal bones. The first metatarsal is connected to the internal cuneiform by a single broad, thin, fibrous band; the second has three dorsal ligaments, one from each cuneiform bone; the third has one from the external cuneiform; the fourth has two, one from the external cuneiform and one from the cuboid; and the fifth, one from the cuboid.

The **plantar ligaments** (*ligamenta tarsometatarsea plantaria*) consist of longitudinal and oblique fibrous bands connecting the tarsal and metatarsal bones, but disposed with less regularity than on the dorsal surface. Those for the first and second metatarsal are the most strongly marked; the second and third metatarsal receive strong fibrous bands which pass obliquely across from the internal cuneiform; the plantar ligaments of the fourth and fifth metatarsal consist of a few scanty fibres derived from the cuboid.

The **interosseous ligaments** (*ligamenta cuneometatarsea interossea*) are three in number—internal, middle, and external. The **internal** one is the strongest of the three, and passes from the outer extremity of the internal cuneiform to the adjacent angle of the second metatarsal. The **middle** one, less strong than the preceding, connects the external cuneiform with the adjacent angle of the second metatarsal. The **external** interosseous ligament connects the outer angle of the external cuneiform with the adjacent side of the third metatarsal.

Synovial Membrane (Fig. 280).—The synovial membrane between the internal cuneiform bone and the first metatarsal bone is a distinct sac. The synovial membrane between the middle and external cuneiform behind, and the second and third metatarsal bones in front, is part of the great tarsal synovial membrane. Two prolongations are sent forward from it—one between the adjacent sides of the second and third metatarsal bones, and one between the third and fourth metatarsal bones. The synovial membrane between the cuboid and the fourth and fifth metatarsal bones is a distinct sac. From it a prolongation is sent forward between the fourth and fifth metatarsal bones.

Movements.—The movements permitted between the tarsal and metatarsal bones are limited to a slight *gliding* upon each other.

VII. The Articulations of the Metatarsal Bones with Each Other (*Articulationes Intermetatarsee*) (Figs. 276, 277).

The base of the first metatarsal bone is not connected with the second metatarsal bone by any ligaments; in this respect it resembles the thumb.

The bases of the four outer metatarsal bones are connected by dorsal, plantar, and interosseous ligaments.

The **dorsal ligaments** (*ligamenta basium* [*oss. metatars.*] *dorsalia*) consist of bands of fibrous tissue which pass transversely between the adjacent metatarsal bones.

The **plantar ligaments** (*ligamenta basium* [*oss. metatars.*] *plantaria*) have a similar arrangement to those on the dorsum.

The **interosseous ligaments** (*ligamenta basium* [*oss. metatars.*] *interossea*) consist of strong transverse fibres which pass between the rough nonarticular portions of the lateral surfaces.

Synovial Membrane.—The synovial membrane between the second and third and the third and fourth metatarsal bones is part of the great tarsal synovial membrane. The synovial membrane between the fourth and fifth metatarsal bones is a prolongation of the synovial membrane of the cubometatarsal joint (Fig. 280).

Movements.—The movement permitted in the tarsal ends of the metatarsal bones is limited to a slight *gliding* of the articular surfaces upon one another.

The Synovial Membranes in the Tarsal and Metatarsal Joints.—The synovial membranes (Fig. 280) found in the articulations of the tarsus and metatarsus are *six* in number—one for the posterior calcaneo-astragaloid articulation; a *second* for the anterior calcaneo-astragaloid and astragaloscaphoid articulations; a *third* for the calcaneocuboid articulation; and a *fourth* for the articulations of the scaphoid with the three cuneiform, the three cuneiform with each other, the external cuneiform with the cuboid, and the middle and external cuneiform with the bases of the second and third metatarsal bones, and the lateral surfaces of the second, third, and fourth metatarsal bones with each other. The *fifth* synovial membrane is found in the articulation of the internal cuneiform with the metatarsal bone of the great toe; and there is a *sixth* for the articulation of the cuboid with the fourth and fifth metatarsal bones. A small synovial membrane is sometimes found between the contiguous surfaces of the scaphoid and cuboid bones.

Nerve Supply.—The nerves supplying the tarsometatarsal joints are derived from the anterior tibial.

FIG. 280.—Oblique section of the articulations of tarsus and metatarsus. Showing the six synovial membranes.

The **digital extremities** of all the metatarsal bones are connected by the **transverse metatarsal ligament**.

The **transverse metatarsal ligament** is a narrow fibrous band which passes transversely across the anterior extremities of all the metatarsal bones, connecting them. It is blended *anteriorly* with the plantar (*glenoid*) ligament of each metatarsophalangeal articulation. To its *posterior border* is connected the fascia covering the Interossei muscles. Its *inferior surface* is concave where the Flexor tendons pass over it. *Above* it the tendons of the Interossei muscles pass to their insertion. It differs from the transverse metacarpal ligament in that it connects the metatarsal bone of the great toe with the rest of the metatarsal bones.

VIII. The Metatarsophalangeal Articulations (*Articulationes Metatarso-phalangeae*).

The metatarsophalangeal articulations are of the condyloid variety, formed by the reception of the rounded heads of the metatarsal bones into shallow cavities in the extremities of the first phalanges. Each joint has a capsule and certain other ligaments. These ligaments are:

Plantar.

Two Lateral.

The **plantar ligaments** (*ligamenta accessoria plantaria*) are thick, dense, fibrous structures. Each is placed on the plantar surface of the joint in the interval between the lateral ligaments, to which it is connected. The plantar ligaments are loosely united to the metatarsal bones, but very firmly to the bases of the first phalanges. The plantar surface of each is intimately blended with the transverse metatarsal ligament, and, except in the great toe, presents a groove for the passage of the Flexor tendons, the sheath surrounding which is connected to each side of the groove. The plantar ligament of the great toe contains two large sesamoid bones. By their deep surface they form part of the articular surface for the head of the metatarsal bone, and are lined with synovial membrane.

The **lateral ligaments** (*ligamenta collateralia*) are strong, rounded cords, placed one on each side of the joint, each being attached, by one extremity, to the posterior tubercle on the side of the head of the metatarsal bone; and, by the other, to the contiguous extremity of the phalanx.

The place of a **dorsal ligament** is supplied by the Extensor tendon over the back of the joint.

Movements.—The movements permitted in the metatarsophalangeal articulations are *flexion*, *extension*, *abduction*, and *adduction*.

IX. The Articulations of the Phalanges (*Articulationes Digitorum Pedis*).

The articulations of the phalanges are ginglymoid joints. Besides the capsular the ligaments are:

Plantar. Two Lateral (*ligamenta collateralia*).

The arrangement of these ligaments is similar to those in the metatarsophalangeal articulations; the Extensor tendon supplies the place of a dorsal ligament.

Movements.—The only movements permitted in the phalangeal joints are *flexion* and *extension*; these movements are more extensive between the first and second phalanges than between the second and third. The movement of flexion is very considerable, but extension is limited by the plantar and lateral ligaments.

Surface Form.—The principal joints which it is necessary to distinguish, with regard to the surgery of the foot, are the *metatarsal* and the *tarsometatarsal*. The joint between the astragalus and the scaphoid is best found by means of the *tubercle of the scaphoid*, for the line of the joint is immediately behind this process. If the foot is grasped and forcibly extended, a rounded prominence, the *head of the astragalus*, will appear on the inner side of the dorsum in front of the ankle-joint, and if a knife is carried downward, just in front of this prominence and behind the line of the scaphoid tubercle, it will enter the astragaloscaphoid joint. The calcaneocuboid joint is situated midway between the external malleolus and the prominent end of the fifth metatarsal bone. The plane of the joint is in the same line as that of the astragaloscaphoid. The position of the joint between the fifth metatarsal bone and the cuboid is easily found by the projection of the fifth metatarsal bone, which is the guide to it. The direction of the line of the joint is very oblique, so that, if continued onward, it would pass through the head of the first metatarsal bone. The joint between the fourth metatarsal bone and the cuboid and external cuneiform is the direct continuation inward of the previous joint, but its plane is less oblique; it would be represented by a line drawn from the outer side of the articulation to the middle of the first metatarsal bone. The plane of the joint between the third metatarsal bone and the external cuneiform is almost transverse. It would be represented by a line drawn from the outer side of the joint to the base of the first metatarsal bone. The tarsometatarsal articulation of the great toe corresponds to a groove which can be felt by making firm pressure on the inner side of the foot one inch in front of the tubercle on the scaphoid bone; and the joint between the second metatarsal bone and the middle cuneiform is to be found on the dorsum of the foot, half an inch behind the level of the tarsometatarsal joint of the great toe. The line of the joints between the metatarsal bones and the first phalanges is about an inch behind the webs of the corresponding toes.

Applied Anatomy.—This is considered on p. 256.

THE MUSCLES AND FASCIÆ.¹

MYOLOGY is the branch of anatomy which treats of the muscles. The muscles are formed of bundles of reddish fibres, endowed notably with the property of contractility in the direction of the long axes of the muscle cells. Contractions of muscle fibres induce motion. The two principal kinds of muscle tissue found in the body are the more highly differentiated, or **voluntary**, and the less highly differentiated, or **involuntary**. The former of these, from the characteristic appearances which its fibres exhibit under the microscope, is known as **striated**, or **striped muscle**. As most striped muscles are capable of being put into action and controlled by the will, they are generally called "voluntary" muscles. The fibres of involuntary muscle do not present any cross-striped appearance, and are not under the control of the will; such muscles are known as **unstriated**, **unstriped** or **vegetative**. The muscle fibres of the heart differ in certain particulars from both these groups, and they are therefore separately described as **cardiac muscle fibres**.

Thus, it will be seen that there are *three* varieties of muscle tissue: (1) Transversely striated fibres, which are for the most part voluntary and under the control of the will. This variety of muscle is also called **skeletal**. (2) Transversely striated muscle fibres, which are not under the control of the will—*i. e.*, the **cardiac muscles**. The cardiac muscle occupies a mid-position in the scale between the cells of involuntary and the striated fibres of voluntary muscle. (3) **Plain or unstriped muscle fibres**, which are involuntary, and are controlled by a different part of the nerve system from that which controls the activity of the voluntary muscles. Such are the muscular walls of the stomach and intestine, of the uterus and bladder, of the bloodvessels, of certain canals and ducts, etc. The statement that striated muscle is *always* voluntary, and that nonstriated muscle is *always* involuntary, cannot be accepted as invariably and inevitably true. There are animals in which some voluntary muscle is free from distinct striation.

Although the voluntary striated muscle tissue alone is concerned in the skeletal musculature, all three varieties of muscle tissue will be described here. The skeletal muscles act upon the bones, and thus produce movement. The primitive contractile elements of a muscle are the **fibres**. Fibres are gathered into groups known as **primary bundles** or **fasciculi**, and the fasciculi are aggregated into masses called **secondary bundles**. In coarse muscles the fasciculi are of considerable size; in fine muscles they are of trivial size. Fasciculi may be long or short, and the length does not depend on the length of the muscle.

Structure of Striated Muscle.—Each muscle is surrounded by a sheath of fibrous tissue called the **epimysium**; this sends in **septa** which surround the secondary bundles; these in turn send in the **perimysium** which surrounds each muscle fasciculus. The fibres of each fasciculus are separated by a delicate meshwork of fibroelastic tissue, the **endomysium**, which supports the small vessels and nerves.

¹The Muscles and Fasciæ are described conjointly, in order that the student may consider the arrangement of the latter in his dissection of the former. It is rare for the student of anatomy in this country to dissect the fasciæ separately; and it is for this reason, as well as from the close connection that exists between the muscles and their investing sheaths, that they are considered together. Some general observations are first made on the histology and anatomy of the muscles and fasciæ, the special description being given in connection with the different regions.

Structure of the Muscle Fibre.—A muscle fibre is a long cylindrical cell varying from one to five inches (2.5 to 12.5 cm.) in length. It is surrounded by a delicate sheath called the **sarcolemma**, within which lie the **nuclei** and **muscle substance**. The muscle substance consists of two elements—the **fibrillae**, or contractile portion of the fibre, and the **sarcoplasm**, or undifferentiated portion. The fibrillae are arranged parallel to one another and are separated by the sarcoplasm; and as the former respond well to the protoplasmic stains, and the latter practically not at all, the alternation of such stained and unstained stripes produces the

FIG. 281.—Two human muscle fibres. $\times 350$. In the one the bundle of fibrillae (b) is torn, and the sarcolemma (a) is seen as an empty tube.

FIG. 282.—A bit of a cross-striated muscle of a frog, showing the nucleus and the ease of its division both transversely and longitudinally. $\times 650$. (Szymonowicz and MacCallum.)

longitudinal striations so typical of the appearance of a longitudinal section of muscle under the microscope. In a cross-section the fibrillae are arranged more or less in groups called **Cohnheim's fields**.

The fibrillae, or **sarcostyle**, are not unbroken threads, but all are interrupted at intervals into short segments called **sarcous elements**. As a result of this segmentation a fibre exhibits alternating transverse dark and light bands (cross-striations). If a muscle fibre be examined under

high magnification, a light line is seen traversing each dark band (anisotropic); this is the **membrane of Hensen**. The light band (isotropic) is traversed by a dark line, **Dobie's line**, or the **membrane of Krause**, that divides the band into two parts, the **lateral disks**. A **sarcomere** is that part of a fibril between two membranes of Krause, and consists of a sarcous element and a lateral disk at each end of the sarcous element.

FIG. 283.—Section of a muscular fibre, showing areas of Cohnheim. Three nuclei are seen lying close to the sarcolemma. (Schafer.)

The nuclei are numerous and are situated peripherally, *i. e.*, just beneath the sarcolemma. They are narrow and elongated in form, and respond readily to the usual stains. Branched fibres are occasionally seen in the tongue. There are two kinds of fibres, *red* and *white*; the *former* are rich in sarcoplasm and the nuclei are deeply placed and are intermediate in development be-

tween myoplasm and the white fibres. The *white* fibres are poor in sarcoplasm and predominate in human muscles. The Trapezius muscle contains both red and white fibres.

The **arteries** of voluntary muscles are numerous. They pierce the epimysium, pass along the septa from the epimysium, and divide into small branches, which enter between the fasciculi. These small branches pass into capillaries which run parallel to the fibres. At intervals dilatable connections (*ampullae*) are established between the capillaries, and it is into

these that during contractions of the muscle the blood passes to relieve the tension in the longitudinal capillaries.

Veins accompany the arteries, and even the smaller ones possess valves (Spalteholz).

The **nerve endings** in voluntary muscle comprise both motor and sensor varieties. A motor nerve pierces the epimysium and breaks up into numerous branches to form an interfascicular plexus in the perimysium. From this plexus nerve fibrils arise, and usually one nerve fibril passes to each muscle fibre. The nerve fibril pierces the sarcolemma, the neurilemma, and myelinic sheath disappearing before the nerve fibril reaches the muscle fibre, and probably being lost by fusing with the sarcolemma. The naked axone beneath the sarcolemma of a fibre continues to the surface of the muscle fibre and undergoes arborization to form an *end organ*. Around the end organ is a quantity of granular sarcoplasm, which, with the nerve and organ, constitutes a **sole plate**. A sensor nerve takes origin from a **muscle spindle**, which consists of a bundle of encapsulated muscle fibres about sensor nerve twigs.

Involuntary striated or cardiac muscle is found in the heart and is not under the control of the will. Each fibre is a short cylinder varying from 100μ to 200μ in length and of about 25μ to 40μ in diameter. The striations are both longitudinal and transverse, but the latter are usually not distinct. Each fibre is surrounded by a delicate membrane. The cells give off narrow processes of branches which connect with each other, thus forming "a reticulum of muscle fibres. The meshes of this reticulum are occupied by areolar tissue in which the vascular and nerve supply of the tissue is situated."

Usually a single, large, oval nucleus occupies the centre of the cell and is surrounded by an area of clear and undifferentiated protoplasm in which fibrillae do not exist. Pigment granules are seen in this undifferentiated protoplasm.

Purkinje fibres are peculiar muscle fibres found in the heart, and will be described with that organ.

The **nerves** are both sympathetic and cerebrospinal.

Involuntary non-striated or smooth muscle is not under the control of the will. It is found in the alimentary tract from the middle third of the oesophagus down, in gland ducts, trachea, bronchi, bronchial tubes, in the urinogenital system, bloodvessels and lymph vessels, etc. It is found arranged in layers that encircle the organs longitudinally, transversely, and sometimes in an interlaced manner.

FIG. 285.—Longitudinal section in the smooth muscle of a dog's large intestine, to show especially intercellular bridges. $\times 530$. (Saymonowicz and MacCallum.)

Each fibre is short and spindle-shaped, varying from 25μ to 200μ in length and from 5μ to 7μ in diameter. In the gravid uterus they are much larger in both dimensions. Occasionally, longitudinal striations are seen, and then the fibrillae so formed are coarse and peripherally located. Each fibre contains a single slender nucleus which is centrally located. **Branched fibres** are occasionally seen in the aorta and in the bladder.

The **bloodvessels** form a meshwork between the fibres.

The **nerves** are from the sympathetic system, though Kuntz has recently shown that in some organs, at least, the nerves are originally derived from the vagus.

Form and Attachment of Muscles.—The muscles are connected with the bones, cartilages, ligaments, and skin, either directly or through the intervention of fibrous structures called **tendons** or **aponeuroses**. Where a muscle is attached to bone or cartilage, the fibres terminate in blunt extremities upon the periosteum

FIG. 284.—Anastomosing muscle fibres of the heart, seen in a longitudinal section. On the right the limits of the separate cells with their nuclei are exhibited somewhat diagrammatically.

or perichondrium, and do not come into direct relation with the osseous or cartilaginous tissue. Where muscles are connected with the skin, they either lie as a flattened layer beneath it, or are connected with its areolar tissue by larger or smaller bundles of fibres, as in the muscles of the face. The origin of a muscle is its **head** (*caput*), while the intermediate portion is called the **belly**, or **venter**.

The muscles vary extremely in their **form**. In the limbs they are of considerable length, especially the more superficial ones, the deep ones being generally broad; they surround the bones and form an important protection to the various joints. In the trunk they are broad, flattened, and expanded, forming the **parietes** of the cavities which they enclose; hence the reason of the terms *long*, *broad*, *short*, etc., used in the description of a muscle.

There is a considerable variation in the arrangement of the fibres of certain muscles with reference to the tendons to which they are attached. In some, the fibres are parallel and run directly from their origin to their insertion; these are **quadrilateral muscles**, such as the Thyrohyoid. A modification of these is found in the **fusiform muscles** in which the muscle tapers at each end; in their action,

FIG. 286.—Diagram of the Deltoid, an example of a multipennate muscle.

however, they resemble the quadrilateral muscles. Secondly, in other muscles the fibres are convergent; arising by a broad origin, they converge to a narrow or pointed insertion. This arrangement of fibres is found in the **triangular muscles**—*e. g.*, the Temporal. In some muscles, which otherwise would belong to the quadrilateral or triangular type, the origin and insertion are not in the same plane, but the plane of the line of origin intersects that of their insertion; such is the case in the Pectineus muscle. Thirdly, in some muscles the fibres are oblique and converge, like the plumes of a pen, to one side of a tendon, which runs the entire length of the muscle. Such a muscle is **penniform** (*m. unipennatus*), as the Peronei. A modification of these muscles is found in those cases where oblique fibres converge to both sides of a central tendon which runs down the

middle of the muscle; these are called **bipenniform** (*m. bipennatus*), and an example is afforded in the Rectus femoris. **Multipennate** muscles are those in which the muscle fibres alternate with a series of tendinous bands, as in the Deltoid. **Biventral** muscles occur, such as the Digastric, while the Rectus abdominis shows subdivision into four or more sections by intervening *inscriptiones tendineae*. Certain muscles do not act in a direct manner, for they or their tendons pass around a bony projection or through a septal pulley (trochlea). Finally, we have muscles in which the fibres are arranged in curved bundles in one or more planes, as in an **orbicular muscle** and in that variety of orbicular muscle called a **sphincter muscle**. The arrangement of the muscle fibres is of considerable importance in respect to their relative strength and range of movement. Those muscles in which the fibres are long and few in number have great range, but diminished strength; where, on the other hand, the fibres are short and more numerous, there is great power, but lessened range.

Muscles differ much in **size**; the Gastrocnemius forms the chief bulk of the back of the leg; the Sartorius is very long; the Stapedius, a small muscle of the internal ear, weighs about a grain, and its fibres are not more than 4 mm. in length.

The names applied to the various muscles have been derived (1) from their *situation*, as the Tibialis, Radialis, Ulnaris, Peroneus; (2) from their *direction*, as

the Rectus abdominis, Obliquus capitis, Transversalis; (3) from their *uses*, as Flexors, Extensors, Abductors, Levators, Compressors, etc.; (4) from their *shape*, as the Deltoid, Trapezius, Rhomboideus, Digastric; (5) from the *number of their divisions*, as the Biceps, the Triceps; (6) from their *points of attachment*, as the Sternomastoid, Sternohyoid, Sternothyroid.

In the description of a muscle the term **origin** is meant to imply its more fixed or central attachment, and the term **insertion**, the movable point to which the force of the muscle is directed; but the origin is absolutely fixed in only a very small number of muscles, such as those of the face, which are attached by one extremity to the bone and by the movable integument; the greater number of muscles can be made to act from either extremity.

In the **dissection** of the muscles, the student should pay especial attention to the exact *origin*, *insertion*, and *actions* of each, and its more important *relations* with surrounding parts. While accurate knowledge of the points of attachment of the muscles is of great importance in the determination of their actions, it is not to be regarded as conclusive. The action of a muscle deduced from its attachments, or even by pulling on it in the dead subject is not necessarily its action in the living. By pulling, for example, on the Brachioradialis in the cadaver the hand may be slightly supinated¹ when in the prone position and slightly pronated when in the supine position, but there is no evidence that these actions are performed by the muscle during life. It is impossible for an individual to throw into action any one muscle; in other words, movements, not muscles, are represented in the central nerve system. To carry out a movement a definite combination of muscles is called into play, and the individual has no power either to leave out a muscle from this combination, or to add one to it. One muscle (or more) of the combination is the chief moving force; when this muscle passes over more than one joint other muscles (**synergic muscles**) come into play to inhibit the movements not required; a third set of muscles (**fixation muscles**) fix the limb—i. e., in the case of the limb movements—and also prevent disturbances of the equilibrium of the body generally. As an example, the movement of the closing of the fist may be considered: (1) The prime movers are the Flexores digitorum, Flexor longus pollicis, and the small muscles of the thumb; (2) the synergic muscles are the Extensores carpi, which prevent flexion of the wrist; while (3) the fixation muscles are the Biceps and Triceps, which steady the elbow and shoulder. A further point which must be borne in mind in considering the actions of muscles is that in certain positions a movement can be effected by gravity, and in such a case the muscles acting are the antagonists of those which might be supposed to be in action. Thus, in flexing the trunk when no resistance is interposed the Erectores spinae contract to regulate the action of gravity, and the Recti abdominis are relaxed.²

By a consideration of the action of the muscles the surgeon is able to explain the causes of displacement in various forms of fracture, and the causes which produce distortion in various deformities, and, consequently, to adopt appropriate treatment in each case. The relations, also, of some of the muscles, especially those in immediate apposition with the larger bloodvessels, and the surface-markings they produce, should be carefully remembered, as they form useful guides in the application of ligatures to those vessels.

Applied Anatomy.—*Degeneration* of muscle tissue is important clinically, and is met with in two main conditions. In one, the degeneration is myopathic, or primary in the muscles themselves; in the other it is neuropathic, or secondary to some lesion of the nerve system—a hemorrhage into the brain, for example, or injury or inflammation of some part of the spinal

¹ Hence the old name *Supinator longus*, now supplanted by Brachioradialis.

² Consult in this connection the Croonian Lectures (1903) on "Muscular Movements and Their Representation in the Central Nervous System," by Charles E. Beevor, M.D.

cord or peripheral nerves. In either case more or less paralysis and atrophy of the affected muscles result. When the degeneration begins primarily in the muscles, however, it often happens that though the muscle fibres waste away, their place is taken by fibrous and fatty tissue to such an extent that the affected muscles increase in volume, and actually appear to hypertrophy.

Ossification of muscle tissue as a result of repeated strain or injury is not infrequent. It is oftenest found about the tendon of the Adductor longus and Vastus internus in horsemen, or in the Pectoralis major and Deltoid of soldiers. It may take the form of exostoses firmly fixed to the bone—*e. g.*, “*rider's bones*” on the femur (page 229)—or of layers or spicules of bone lying in the muscles of their fasciæ and tendons. Busse states that these bony deposits are preceded by a hemorrhagic myositis due to injury, the effused blood organizing and being finally converted into bone. In the rarer disease, progressive *myositis ossificans*, there is an unexplained tendency for practically any of the voluntary muscles to become converted into solid and brittle bony masses which are completely rigid.

Tendons are white, glistening, fibrous cords, varying in length and thickness, sometimes round, sometimes flattened, of considerable strength, and devoid of elasticity. They consist almost entirely of dense, white fibrous tissue, the fibrils of which run in an undulating parallel course and are firmly united together. They are very sparingly supplied with bloodvessels, the smaller tendons presenting not a trace of them in their interior. Nerves supplying tendons have special modifications of their terminals, termed neurotendinous spindles or organs of Golgi.

Aponeuroses are flattened or ribbon-shaped tendons, of a pearly-white color, iridescent, glistening, and similar in structure to the tendons. They are destitute of nerves, and the thicker ones are only sparingly supplied with bloodvessels.

The tendons and aponeuroses are connected, on the one hand, with the muscles, and, on the other hand, with movable structures, as the bones, cartilages, ligaments, fibrous membranes (for instance, the sclera). Where the muscle fibres are in a direct line with those of the tendon or aponeurosis, the two are directly continuous, the muscle fibre being distinguishable from that of the tendon only by its striation and increase of muscle nuclei. But where the muscle fibres join the tendon or aponeurosis at an oblique angle the former terminate, according to Kölliker, in rounded extremities, which are received into corresponding depressions on the surface of the latter, the connective tissue between the fibres being continuous with that of the tendon. The latter mode of attachment occurs in all the penniform and bipenniform muscles, and in those muscles the tendons of which commence in a membranous form, as the Gastrocnemius and Soleus.

The **fasciæ** are fibroareolar or aponeurotic laminæ of variable thickness and strength, found in all regions of the body, investing the softer and more delicate organs. The fasciæ have been subdivided, from the situation in which they are found, into two groups, **superficial** and **deep**.

The **superficial fascia** (*panniculus adiposus*) is found immediately beneath the integument over almost the entire surface of the body. It connects the skin with the deep or aponeurotic fascia, and consists of fibroareolar tissue, containing in its meshes pellicles of fat, in varying quantity. In the eyelids and scrotum, where adipose tissue is rarely deposited, this tissue is very liable to serous infiltration. The superficial fascia varies in thickness in different parts of the body: in the groin it is so thick as to be capable of being subdivided into several laminæ. Beneath the fatty layer of the superficial fascia, which is immediately subcutaneous, there is generally another layer of the same structure, comparatively devoid of adipose tissue, in which the trunks of the subcutaneous vessels and nerves are found, as the superficial epigastric vessels in the abdominal region, the radial and ulnar veins in the forearm, the saphenous veins in the leg and thigh, and the superficial lymph nodes. Certain cutaneous muscles also are situated in the superficial fascia, as the Platysma in the neck, and the Orbicularis palpebrarum around the eyelids. This fascia is most distinct at the lower part of the abdomen, the scrotum, perineum, and extremities; it is very thin in those regions where

muscle fibres are inserted into the integument, as on the side of the neck, the face, and around the margin of the anus. It is very dense in the scalp, in the mammae, the palms of the hands and soles of the feet, forming a fibrofatty layer which binds the integument firmly to the subjacent structure.

The superficial fascia connects the skin to the subjacent parts, facilitates the movement of the skin, serves as a soft medium for the passage of vessels and nerves to the integument, and retains the warmth of the body, since the fat contained in its areolæ is a poor conductor of heat.

The **deep** or **aponeurotic** fascia is a dense, inelastic, unyielding fibrous membrane, forming sheaths for the muscles and affording them broad surfaces for attachment. It consists of shining tendinous fibres, placed parallel to one another, and connected by other fibres disposed in a rectilinear manner. It is usually exposed on the removal of the superficial fascia, forming a strong investment, which not only binds down collectively the muscles in each region, but gives a separate sheath to each, as well as to the vessels and nerves. The fasciæ are thick in unprotected situations, as on the outer side of a limb, and thinner on the inner side. The deep fasciæ assist the muscles in their action by the degree of tension and pressure they make upon their surface; and in certain situations this is increased and regulated by muscular action; as, for instance, by the Tensor fasciæ femoris and Gluteus maximus in the thigh, by the Biceps in the upper and lower extremities, and Palmaris longus in the hand. In the limbs the fasciæ not only invest the entire limb, but give off septa which separate the various muscles, and are deeply attached to the periosteum; these prolongations of fasciæ are usually spoken of as *intermuscular septa*.

Development of the Skeletal Musculature.—The voluntary muscles are developed from the myotomes of the mesodermal somites. Portions of the myotomes retain their position along the body axis in segmental order, such as the short muscles of the vertebral column. Others migrate into the body wall, where again they may retain their segmental relation (intercostal muscles), or may fuse with adjacent segments to form flat muscles such as those in the abdominal wall. In the *limbs*, portions of myotomes wander into the limb buds and there undergo fusions and alterations in form to produce the limb muscles, thus losing their segmental character, but retaining the appropriate segmental nerve supplies. Some of the limb muscles expand and migrate secondarily toward the dorsimesal line (*e. g.*, Trapezius, Latissimus) or toward the ventromesal line (*e. g.*, Pectoralis major). Again, muscles may migrate cephalad (*e. g.*, the facial muscles derived from the hyoid arch) or caudad (*e. g.*, Serratus magnus). In all cases the muscles carry with them the segmental nerves of the myotomes from which they were derived; the most striking example is the Diaphragm which is derived from the third, fourth, and fifth cervical myotomes, and is supplied by the phrenic nerves, which spring from the third, fourth, and fifth cervical nerves. Some of the derivatives of the myotomes degenerate and are converted into aponeuroses (*e. g.*, epicranial aponeurosis) or into ligaments (*e. g.*, great sacrosciatic ligament and external lateral ligament of the knee).

Various disturbances of development characterize what are known as **variable** or **anomalous muscles**. Such muscles may be wanting, or excessively developed in the way of accessory portions or with atypic attachments. The resemblance which such muscles in the human subject bear to certain muscles in lower animals has been regarded by some anatomists as an expression of atavistic reversion.¹

The **muscles** and **fasciæ** may be arranged according to the general division of the body, into those of the **cranium**, **face**, and **neck**; those of the **trunk**; those of the **upper extremity** or **pectoral limb**; and those of the **lower extremity** or **pelvic limb**.

¹ See, however, Huntington, American Journal of Anatomy, 1902-03, vol. ii, p. 157.

MUSCLES AND FASCIÆ OF THE CRANIUM AND FACE.

The muscles of the cranium and face consist of ten groups, arranged according to the region in which they are situated:

- | | |
|----------------------|-------------------------------|
| 1. Cranial Region. | 6. Maxillary Region. |
| 2. Auricular Region. | 7. Mandibular Region. |
| 3. Palpebral Region. | 8. Buccal Region. |
| 4. Orbital Region. | 9. Temporomandibular Region. |
| 5. Nasal Region. | 10. Pterygomandibular Region. |

The muscles contained in each of these groups are the following:

- | | |
|---|--|
| 1. <i>Cranial Region.</i>
Occipitofrontalis. | 6. <i>Maxillary Region.</i>
Levator labii superioris.
Levator anguli oris.
Zygomaticus major.
Zygomaticus minor. |
| 2. <i>Auricular Region.</i>
Attrahens aurem.
Attollens aurem.
Retrahens aurem. | 7. <i>Mandibular Region.</i>
Levator menti.
Depressor labii inferioris.
Depressor anguli oris. |
| 3. <i>Palpebral Region.</i>
Orbicularis palpebrarum.
Corrugator supercilii.
Tensor tarsi. | 8. <i>Buccal Region.</i>
Buccinator.
Risorius.
Orbicularis oris. |
| 4. <i>Orbital Region.</i>
Levator palpebrae.
Rectus superior.
Rectus inferior.
Rectus internus.
Rectus externus.
Obliquus oculi superior.
Obliquus oculi inferior. | 9. <i>Temporomandibular Region.</i>
Masseter.
Temporal. |
| 5. <i>Nasal Region.</i>
Pyramidalis nasi.
Levator labii superioris alaeque nasi.
Dilatator naris posterior.
Dilatator naris anterior.
Compressor nasi.
Compressor narium minor.
Depressor alae nasi. | 10. <i>Pterygomandibular Region.</i>
Pterygoideus externus.
Pterygoideus internus. |

1. The Cranial Region.

Occipitofrontalis.

Dissection (Fig. 287).—The head being shaved, and a block placed beneath the back of the neck, make a vertical incision through the skin, commencing at the root of the nose in front,

and terminating behind at the occipital protuberance; make a second incision in a horizontal direction along the forehead and around the side of the head, from the anterior to the posterior extremity of the preceding. Raise the skin in front, from the subjacent muscle, from below upward; this must be done with extreme care, removing the integument from the outer surface of the vessels and the nerves which lie immediately beneath the skin.

The Skin of the Scalp.—This is thicker than in any other part of the body. It is intimately adherent to the superficial fascia, which attaches it firmly to the underlying aponeurosis and muscle. Movements of the muscle move the skin. The hair follicles are very closely set together, and extend throughout the whole thickness of the skin. It also contains a number of sebaceous glands.

FIG. 287.—Dissection of the head, face, and neck.

The **superficial fascia** in the cranial region is a firm, dense, fibrofatty layer, intimately adherent to the integument, and to the Occipitofrontalis and its tendinous aponeurosis; it is continuous, behind, with the superficial fascia at the back part of the neck; and, laterally, is continued over the temporal fascia. It contains between its layers the superficial vessels and nerves and much fat.

FIG. 288.—Epicranial aponeurosis. Antero-posterior section. (Schematic.) (Poirier and Charpy.)

The **Occipitofrontalis** (*m. epicranius*) (Fig. 289) is a broad musculofibrous layer, which covers the whole of one side of the vertex of the skull, from the occiput to the eyebrow. It consists of two muscle slips, separated by an intervening tendinous aponeurosis. The occipital portion, the **occipitalis muscle** (*m. occipitalis*)

is thin, quadrilateral in form, and about an inch and a half in length; it *arises* from the outer two-thirds of the superior curved line of the occipital bone, and from the mastoid portion of the temporal bone. Its fibres of origin are tendinous, but they are soon succeeded by muscle fibres, and ascend in a parallel direction to *terminate* in a tendinous aponeurosis. The frontal portion, the **frontalis muscle** (*m. frontalis*), is thin, of a quadrilateral form, and intimately adherent to the super-

FIG. 289.—Muscles of the head, face, and neck.

ficial fascia. It is broader, its fibres are longer, and their structures paler than the occipital portion. It has no bony attachments. Its internal fibres are continuous with those of the *Pyramidalis nasi*. Its middle fibres become blended with the *Corrugator supercilii* and *Orbicularis palpebrarum*; and the outer fibres are also blended with the latter muscle over the external angular process. From these attachments the fibres are directed upward, and join the aponeurosis in front of

the coronal suture. The inner margins of the frontal portions of the two muscles are joined together for some distance above the root of the nose; but between the occipital portions there is a considerable, though variable, interval, which is occupied by the aponeurosis.

The **epicranial aponeurosis** (*galea aponeurotica*) covers the upper part of the vertex of the skull, being continuous across the middle line with the aponeurosis of the opposite muscle. *Behind*, it is attached, in the interval between the occipital origins, to the occipital protuberance and highest curved lines of the occipital bone; in front, it forms a short and narrow prolongation between the frontal portions; and on each side it gives origin to the Attollens and Attrahens aurem muscles of the pinna. This aponeurosis is closely connected to the integument by the firm, dense, fibrofatty layer which forms the superficial fascia; it is connected with the pericranium by loose cellular tissue, which allows of a considerable degree of movement of the integument. It is continuous with the temporal fascia below the temporal ridge, and it is in reality the representative of the deep fascia.

Nerves.—The frontal portion of the Occipitofrontalis is supplied by the temporal branches of the facial nerve; its occipital portion by the posterior auricular branch of the facial.

Actions.—The frontal portion of the muscle raises the eyebrows and the skin over the root of the nose, and at the same time draws the scalp forward, throwing the integument of the forehead into transverse wrinkles. The posterior portion draws the scalp backward. By bringing alternately into action the frontal and occipital portions the entire scalp may be moved forward and backward. In the ordinary action of the muscles, the eyebrows are elevated, and at the same time the aponeurosis is fixed by the posterior portion, thus giving to the face the expression of surprise; if the action is more exaggerated, the eyebrows are still further raised, and the skin of the forehead thrown into transverse wrinkles, as in the expression of fright or horror.

Applied Anatomy.—The skull is covered by the *scalp* (Fig. 288). This consists, from without inward, of *five layers*: (1) Skin; (2) subcutaneous fat; (3) the Occipitofrontalis muscle and aponeurosis; (4) a layer of connective tissue beneath the Occipitofrontalis aponeurosis (subaponeurotic tissue); (5) the pericranium. The subcutaneous tissue is composed of bands of fibrous tissue enclosing spaces filled with fat. The fibrous character of this tissue greatly limits discoloration and swelling when inflammation occurs. The edges of a wound which does not involve the aponeurosis or muscle do not retract, hence the wound does not gape. The bloodvessels run practically in the skin, and as they lie in very dense tissue and are adherent to it, wounds bleed profusely, the arteries being unable freely to contract and retract. It is very difficult or impossible to pick up with forceps a vessel in the skin of the scalp, and bleeding must be arrested by suture ligatures or by the stitches which close the wound. Sebaceous glands in the skin of the scalp may develop into *sebaceous cysts* (wens). If a wound involves the muscle or aponeurosis, it gapes widely, the greatest amount of gaping being observed in transverse wounds. The space between the aponeurosis and the pericranium is called by Treves *the dangerous area of the scalp*. It contains a layer of connective tissue, and suppuration in this tissue spreads widely. An *abscess* in the dangerous area should be opened above the superior curved line of the occipital bone, above the eyebrow or above the zygoma. In a wound or contusion superficial to the aponeurosis but little blood can be effused in the tissue because its fibrous structure prevents it, and abscesses do not tend to spread widely. Between the aponeurosis and the pericranium a great amount of blood can be effused. An effusion of blood beneath the pericranium is called a *cephalhematoma*. Such a condition may occur from pressure during birth. An extravasation beneath the pericranium is limited to the surface of one bone. The pericranium is tightly attached to the sutures, but adheres lightly to the surface of the bone, and abscess beneath the pericranium is restricted to the surface of one bone.

2. The Auricular Region (Fig. 289).

Attrahens aurem.

Attollens aurem.

Retrahens aurem.

These three small muscles are placed immediately beneath the skin, around the external ear. In man, in whom the external ear is almost immovable, they are

rudimentary. They are the homologues of large and important muscles in some of the mammalia.

Dissection.—This requires considerable care, and should be performed in the following manner: To expose the Attollens aurem, draw the pinna, or broad part of the ear, downward, when a tense band will be felt beneath the skin, passing from the side of the head to the upper part of the concha; by dividing the skin over this band in a direction from below upward, and then reflecting it on each side, the muscle is exposed. To bring into view the Attrahens aurem, draw the helix backward by means of a hook, when the muscle will be made tense, and may be exposed in a similar manner to the preceding. To expose the Retrahens aurem, draw the pinna forward, when the muscle, being made tense, may be felt beneath the skin at its insertion into the back part of the concha, and may be exposed in the same manner as the other muscles.

The **Attrahens aurem** (*m. auricularis anterior*), the smallest of the three, is thin, fan-shaped, and its fibres pale and indistinct; they arise from the lateral edge of the aponeurosis of the Occipitofrontalis, and converge to be inserted into a projection of the front of the helix.

The **Attollens aurem** (*m. auricularis superior*), the largest of the three, is thin and fan-shaped; its fibres arise from the aponeurosis of the Occipitofrontalis and converge to be inserted by a thin, flattened tendon into the upper part of the cranial surface of the pinna.

The **Retrahens aurem** (*m. auricularis posterior*) consists of two or three fleshy fasciculi, which arise from the mastoid portion of the temporal bone by short aponeurotic fibres. They are inserted into the lower part of the cranial surface of the concha.

Nerves.—The Attrahens and Attollens aurem are supplied by the temporal branch of the facial; the Retrahens aurem is supplied by the posterior auricular branch of the same nerve.

Actions.—In man, these muscles possess very little action: the Attrahens aurem draws the pinna forward and upward; the Attollens aurem slightly raises it; and the Retrahens aurem draws it backward.

3. The Palpebral Region (Fig. 289).

Orbicularis palpebrarum.
Corrugator supercilii.

Levator palpebrae.
Tensor tarsi.

Dissection (Fig. 287).—In order to expose the muscles of the face, continue the longitudinal incision made in the dissection of the Occipitofrontalis down the median line of the face to the tip of the nose, and from this point onward to the upper lip; and carry another incision along the margin of the lip to the angle of the mouth, and transversely across the face to the angle of the mandible. Then make an incision in front of the external ear, from the angle of the mandible upward; to join the transverse incision made in exposing the Occipitofrontalis. These incisions include a square-shaped flap, which should be removed in the direction marked in the figure, with care, as the muscles at some points are intimately adherent to the integument.

The **Orbicularis palpebrarum** (*m. orbicularis oculi*) is a sphincter muscle, which surrounds the circumference of the orbit and eyelids. It arises from the internal angular process of the frontal bone, from the frontal process of the maxilla in front of the lacrimal groove for the nasal duct, and from the anterior surface and borders of a short tendon, the **tendo oculi**, or **internal tarsal ligament**, placed at the inner angle of the orbit. From this origin the fibres are directed outward, forming a broad, thin, and flat layer, which covers the eyelids, surrounds the circumference of the orbit, and spreads out over the temple and downward on the cheek. The **internal or palpebral portion** (*pars palpebralis*) of the Orbicularis is thin and pale; it arises from the bifurcation of the tendo oculi, and forms a series of concentric curves, which are on the outer side of the eyelids inserted into the **external tarsal ligament**. The **external or orbital portion** (*pars orbitalis*) is thicker and of a reddish color; its fibres are well developed, and form complete

ellipses. The upper fibres of this portion blend with the Occipitofrontalis and Corrugator supercilii.

Relations.—By its *superficial surface*, with the integument. By its *deep surface*, above, with the Occipitofrontalis and Corrugator supercilii, with which it is intimately blended, and with the supraorbital vessels and nerve; below, it covers the lacrimal sac, and the origin of the Levator labii superioris alaeque nasi, the Levator labii superioris, and the Zygomaticus minor muscles. *Internally*, it is occasionally blended with the Pyramidalis nasi. *Externally*, it lies on the temporal fascia. On the eyelids it is separated from the conjunctiva by the Levator palpebrae, the tarsal ligaments, the tarsal plates, and the Meibomian glands.

The **tendo oculi** or **internal tarsal ligament** (*ligamentum palpebrale mediale*) is a short tendon, about one-sixth of an inch in length and half as much in breadth, attached to the frontal process of the maxilla in front of the lacrimal groove. Crossing the lacrimal sac, it divides into two parts, each division being attached to the inner extremity of the corresponding tarsal plate. As the tendon crosses the lacrimal sac, a strong aponeurotic lamina is given off from the posterior surface, which expands over the sac, and is attached to the ridge on the lacrimal bone. This is the **reflected aponeurosis** of the tendo oculi.

The **external tarsal ligament** (*raphé palpebralis lateralis*) is a much weaker structure than the tendo oculi. It is attached to the margin of the frontal process of the malar bone, and passes inward to the outer commissure of the eyelid, where it divides into two slips, which are attached to the margins of the two tarsal plates.

USE OF TENDO OCULI.—Besides giving attachment to part of the Orbicularis palpebrarum and to the tarsal plates, it serves to suck the tears into the lacrimal sac, by its attachment to the sac. Thus, each time the eyelids are closed, the tendo oculi becomes tightened, through the action of the Orbicularis, and draws the wall of the lacrimal sac outward and forward, so that a vacuum is made in the sac, and the tears are sucked along the lacrimal canals into it.

The **Corrugator supercilii** (Figs. 288 and 289) is a small, narrow, pyramidal muscle, placed at the inner extremity of the eyebrow, beneath the Occipitofrontalis and Orbicularis palpebrarum muscles. It *arises* from the inner extremity of the superciliary ridge, from whence its fibres pass upward and outward between the palpebral and orbital portions of the Orbicularis palpebrarum, and are *inserted* into the deep surface of the skin, opposite the middle of the orbital arch.

Relations.—By its *superficial surface* with the Occipitofrontalis and Orbicularis palpebrarum muscles; by its *deep surface*, with the frontal bone and supratrochlear nerve.

The **Tensor tarsi** or **Horner's muscle** (*pars lacrimalis m. orbicularis palpebrarum*) (Fig. 290) is a small thin muscle about a quarter of an inch in breadth and half an inch in length, situated at the inner side of the orbit, behind the tendo oculi and lacrimal sac. It *arises* from the crest and adjacent part of the orbital surface of the lacrimal bone, and, passing across the lacrimal sac, divides into two slips, which cover the lacrimal canals and are *inserted* into the tarsal plates internal to the puncta lacrimalia. Its fibres appear to be continuous with those of the palpebral portion of the Orbicularis palpebrarum; it is occasionally very indistinct.

Nerves.—The Orbicularis palpebrarum, Corrugator supercilii, and Tensor tarsi are supplied by the facial nerve.

Actions.—The Orbicularis palpebrarum is the sphincter muscle of the eyelids. The palpebral portion acts involuntarily, closing the lids gently, as in sleep, or in blinking; the orbicular portion is subject to the will. When the entire muscle is brought into action, the skin of the forehead, temple, and cheek is drawn inward toward the inner angle of the orbit, and the eyelids are firmly closed as in photophobia. When the skin of the forehead, temple, and cheek is thus drawn inward by the action of the muscle it is thrown into folds, especially radiating from the

outer angle of the eyelids, which give rise in old age to the so-called "crow's feet." The *Levator palpebrae* is the direct antagonist of this muscle; it raises the upper eyelid and exposes the globe of the eye. The *Corrugator supercilii* draws the eyebrow downward and inward, producing the vertical wrinkles of the forehead. It is the "frowning" muscle, and may be regarded as the principal agent in the expression of suffering. The *Tensor tarsi* draws the eyelids inward and compresses the eyelids and the extremities of the lacrimal canals against the surface of the globe of the eye; thus placing the canals in the most favorable situation for receiving the tears. It serves, also, to compress the lacrimal sac.

FIG. 290.—The three portions of the *Orbicularis palpebrarum* muscle, and the relation of this muscle to the *Corrugator supercilii* muscle, seen from behind. (Left side.) (Toldt.)

4. The Orbital Region (Fig. 292).

<i>Levator palpebrae superioris.</i>	<i>Rectus internus.</i>
<i>Rectus superior.</i>	<i>Rectus externus.</i>
<i>Rectus inferior.</i>	<i>Obliquus oculi superior.</i>
<i>Obliquus oculi inferior.</i>	

Dissection.—To open the cavity of the orbit, remove the skullcap and brain; then saw through the frontal bone at the inner extremity of the supraorbital ridge, and externally at its junction with the malar. Break in pieces the thin roof of the orbit by a few slight blows of the hammer, and take it away; drive forward the superciliary portion of the frontal bone by a smart stroke, but do not remove it, as that would destroy the pulley of the *Obliquus superior*. When the fragments are cleared away, the periosteum of the orbit will be exposed; this being removed, together with the fat which fills the cavity of the orbit, the several muscles of this region can be examined. The dissection will be facilitated by distending the globe of the eye. In order to effect this, puncture the optic nerve near the eyeball with a curved needle, and push the needle onward into the globe; insert the point of a blowpipe through this aperture, and force a little air into the cavity of the eyeball; then apply a ligature around the nerve so as to prevent the air escaping. The globe being now drawn forward, the muscles will be put upon the stretch.

Orbital Septum.—Subjacent to the *Orbicularis palpebrarum* a dense fascial sheet supports the tarsal plates and serves as a septum (*septum orbitale*), which is attached to the orbital margin. It is perforated by the small vessels and

nerves which supply the integument of the eyelids. The tarsal ligaments previously described are reënforcing bands of this fascial septum.

The **Levator palpebrae superioris** is thin, flat, and triangular in shape. It *arises* from the under surface of the lesser wing of the sphenoid, above and in front of the optic foramen, from which it is separated by the origin of the Superior

FIG. 291.—Sagittal section of left orbital cavity.

rectus (Fig. 293). At its origin it is narrow and tendinous, but soon becomes broad and fleshy, and terminates anteriorly in a wide aponeurosis, which splits into three lamellæ. The *superficial lamella blends* with the superior palpebral ligament, and is prolonged forward above the superior tarsal plate to the palpebral part of the Orbicularis palpebrarum and to the deep surface of the skin of the

FIG. 292.—Muscles of the right orbit.

upper eyelid. The *middle lamella*, largely made up of unstriated muscle fibres (*superior tarsal muscle*), is inserted into the upper margin of the superior tarsal plate, while the *deepest lamella blends* with an expansion from the sheath of the Superior rectus muscle and with it is attached to the superior fornix of the conjunctiva.

Relations.—By its *orbital surface*, with the frontal nerve and supraorbital artery, the periosteum of the orbit and lacrimal gland; and, in the lid, with the inner surface of the tarsal ligament; by its *ocular surface*, with the Superior rectus, and, in the lid, with the conjunctiva. A small branch of the oculomotor nerve enters its under surface.

The four **Recti** (Fig. 293) arise from a fibrous ring (*annulus tendineus communis*) which surrounds the upper, inner, and lower margins of the optic foramen and encircles the optic nerve. Two specialized parts may be made out: (1) A *lower*, the **tendon or ligament of Zinn**, which gives *origin* to the Inferior rectus, part of the Internal rectus, and the lower head of the External rectus; and (2) an *upper*, the **superior tendon of Lockwood**, which gives *origin* to the Superior rectus, the rest of the Internal rectus, and the upper head of the External rectus.

Each of the four Recti passes forward in the position implied by its name, to be *inserted* by a tendinous expansion into the sclera, about a quarter of an inch from the margin of the cornea. Between the two heads of the External rectus is a narrow interval, through which pass the two divisions of the oculomotor nerve, the nasal branch of the ophthalmic division of the trigeminal nerve, the abducent nerve, and the ophthalmic vein. Of the four Recti, the Internal rectus is the broadest, the External the longest, and the Superior the thinnest and narrowest.

FIG. 293.—The relative position and attachment of the muscles of the left eyeball.

The **Superior oblique** (*m. obliquus oculi superior*) is a fusiform muscle placed at the upper and inner side of the orbit, internal to the Levator palpebrae. It arises a little above the inner margin of the optic foramen (Fig. 293), and, passing forward to the inner

angle of the orbit, terminates in a rounded tendon, which plays in a fibrocartilaginous ring or pulley, the **trochlea** (*trochlea m. obliqui oculi superioris*), attached to the trochlear fossa near the internal angular process of the frontal bone. The contiguous surfaces of the tendon and ring are lined with a delicate synovial membrane and are enclosed in a thin fibrous investment. The tendon is reflected backward, outward, and downward beneath the Superior rectus to the outer part of the globe of the eye, and is *inserted* into the sclera, behind the equator of the eyeball, the insertion of the muscle lying between the Superior and External recti.

Relations.—By its *orbital surface*, with the periosteum covering the roof of the orbit and the trochlear nerve; the tendon, where it lies on the globe of the eye, is covered by the Superior rectus; by its *ocular surface*, with the nasal nerve, ethmoidal arteries, and the upper border of the Internal rectus.

The **Inferior oblique** (*m. obliquus oculi inferior*) is a thin, narrow muscle placed near the anterior margin of the orbit. It arises from a depression on the orbital plate of the maxilla, external to the lacrimal groove (Fig. 292). Passing outward, backward, and upward between the Inferior rectus and the floor of the orbit, and then between the eyeball and the External rectus, it is *inserted* into the outer part of the sclera between the Superior and External recti, near to, but somewhat behind, the tendon of insertion of the Superior oblique. Beyond its insertion a thin layer of non-striated muscle fibres (*inferior tarsal muscle*) continues into the lower eyelid to be inserted into the inferior tarsal plate.

Relations.—By its *ocular surface*, with the globe of the eye and with the Inferior rectus; by its *orbital surface*, with the periosteum covering the floor of the orbit, and with the External rectus. Its borders look forward and backward; the posterior one receives a branch of the motor oculi nerve.

The orbital muscle, or Müller's muscle (*musculus orbitale*), which spans the sphenomaxillary fissure and infraorbital groove, is composed of nonstriated fibres, and is a rudimentary structure continuous with the periosteum of the orbit.¹

Nerves.—The Levator palpebrae, Inferior oblique, and all the Recti excepting the External are supplied by the oculomotor nerve; the Superior oblique, by the trochlear; the External rectus, by the abducent.

Actions.—The Levator palpebrae raises the upper eyelid, and is the direct antagonist of the Orbicularis palpebrarum. The four Recti muscles are attached in such a manner to the globe of the eye that, acting singly, they will turn its corneal surface either upward, downward, inward, or outward, as expressed by their names. The movement produced by the Superior or Inferior rectus is not quite a simple one, for, inasmuch as they pass obliquely outward and forward to the eyeball, the elevation or depression of the cornea must be accompanied by a certain deviation inward, with a slight amount of rotation. These latter movements are corrected by the Oblique muscles, the Inferior oblique correcting the deviation inward of the Superior rectus, and the Superior oblique that of the Inferior rectus. The contraction of the External and Internal recti, on the other hand, produces a purely horizontal movement. If any two contiguous Recti of one eye act together, they carry the globe of the eye in the diagonal of these directions—viz., upward and inward, upward and outward, downward and inward, or downward and outward. The movement of circumduction, as in looking around a room, is performed by the alternate action of the four Recti. The Oblique muscles rotate the eyeball on its *antero-posterior axis*, this kind of movement being required for the correct viewing of an object when the head is moved laterally, as from shoulder to shoulder, in order that the picture may fall in all respects on the same part of the retina of either eye. Sometimes the corresponding Recti and sometimes the opposite ones of the two eyes act together; for instance, the two Superior and Inferior recti carry both eyeballs upward and downward, respectively. In looking toward the right, the right External and left Internal recti act together, the reverse being the case in looking toward the left. In turning both eyes toward the middle line, as in directing our vision toward an object less than twenty feet distant, the two Internal recti act together.

Fascia of the Orbit.—The connective tissue of the orbit is in various places condensed into thin membranous layers, which may be conveniently described as (1) the orbital fascia; (2) the sheaths of the muscles; and (3) the fascia of the eyeball.

1. **The Orbital Fascia.**—This forms the periosteum of the orbit. It is loosely connected to the bones, from which it can be readily separated. *Behind*, it is connected with the dura by processes which pass through the optic foramen and sphenoidal fissure, and with the sheath of the optic nerve. *In front* it is connected with the periosteum at the margin of the orbit, and sends off a process which assists in forming the palpebral fascia or orbital septum. From its internal surface two processes are given off—one to enclose the lacrimal gland, the other to hold the pulley of the Superior oblique muscle in position. A layer of nonstriated muscle, the orbital muscle of H. Müller, spans the sphenomaxillary fissure and stray fibres of nonstriated muscle extend along the periosteum of the lateral wall of the orbit.

2. **The Sheaths of the Muscles.**—The sheaths of the muscles give off expansions to the margins of the orbit which limit the action of the muscles.

3. **The Fascia of the Eyeball.**—*Ténon's capsule*—surrounds the posterior two-thirds of the eyeball; it will be described with the anatomy of the eyeball.

Applied Anatomy.—The position and exact point of insertion of the tendons of the Internal and External recti muscles into the globe should be carefully examined from the front of the eyeball, as the surgeon is often required to divide the one or the other muscle for the cure of *strabismus* (squint). In convergent strabismus, which is the more common form of the disease, the eye is turned inward, requiring the division of the Internal rectus. In the divergent form which is more rare, the eye is turned outward, the External rectus being especially implicated. The deformity produced in either case is to be remedied by division of one or the other muscle. The operation is thus performed: The lids are to be well separated; the eyeball being rotated outward or inward, the conjunctiva should be raised by a pair of forceps and divided immediately beneath the lower border of the tendon of the muscle to be divided, a little behind its insertion into the sclera; the submucous areolar tissue is then divided, and into the small aperture thus made a blunt hook is passed upward between the muscle and the globe, and the tendon of the muscle and conjunctiva covering it divided by a pair of blunt-pointed scissors. Or the tendon may be divided by a subconjunctival incision, one blade of the scissors being passed upward between the tendon and the conjunctiva, and the other between the tendon and the sclera. Inflammation of the synovial membrane lining the trochlea of the Superior oblique may lead to the formation of a *cyst* of considerable size.

¹ See F. Groyer, in the Vienna Sitzungsberichte der Kaiserlichen Akademie der Wissenschaften, 1903, Band cxii.

In performing *enucleation of the eyeball* the conjunctiva is clipped with scissors near the corner and the capsule of Ténon is divided with it. One Rectus muscle after another is caught up on a blunt hook and divided. The scissors are now pushed well in along the outer orbital wall and the optic nerve is divided. Finally, the Oblique muscles, the ciliary vessels and nerves, and fragments of tissue helping to retain the globe are cut and the eyeball is enucleated.

An *orbital abscess* is evacuated by making an incision close to the border of the orbit, above or below the eyeball.

Exophthalmos, or abnormal protrusion of the eyeball, is believed to be due to hypersecretion of the thyroid (as in goitre), which, through the cervicocephalic division of the sympathetic, stimulates the nonstriated tarsal muscles to sustained contraction. These muscles are arranged like a cuff, and may be regarded as having their origin in the orbital septum and their insertion at the equator of the eyeball. In their action they are antagonists of the Recti, and of the Levator palpebrae superioris, and open wide the palpebral fissure and draw the eyeball forward. (Consult J. Landström, Ueber Morbus Basedowii, Thesis, Stockholm, 1907.)

5. The Nasal Region (Fig. 289).

Pyramidalis nasi.

Levator labii superioris alaeque nasi.

Dilatator naris posterior.

Dilatator naris anterior.

Compressor nasi.

Compressor narium minor.

Depressor alae nasi.

The **Pyramidalis nasi** (*m. procerus*) is a small pyramidal slip placed over the nasal bone. Its *origin* is by tendinous fibres from the fascia covering the lower part of the nasal bone and upper part of the cartilage, where it blends with the Compressor nasi, and it is *inserted* into the skin over the lower part of the forehead between the two eyebrows, its fibres decussating with those of the Occipitofrontalis (see page 364).

The **Levator labii superioris alaeque nasi** is a thin triangular muscle placed by the side of the nose, and extending between the inner margin of the orbit and upper lip. It *arises* by a pointed extremity from the upper part of the nasal process of the maxilla, and, passing obliquely downward and outward, divides into two slips, one of which is *inserted* into the cartilage of the ala of the nose; the other is prolonged into the upper lip, becoming attached to the under surface of the skin and blended with the Orbicularis oris and Levator labii superioris proprius.

The **Dilatator naris posterior** is a small muscle which is placed partly beneath the elevator of the nose and lip. It *arises* from the margin of the nasal notch of the maxilla and from the sesamoid cartilages, and is *inserted* into the skin near the margin of the nostril.

The **Dilatator naris anterior** is a thin, delicate fasciculus passing from the cartilage of the ala of the nose to the integument near its margin. This muscle is situated in front of the preceding.

The **Compressor naris** (*m. nasalis*) is a small, thin, triangular muscle *arising* by its apex from the maxilla, above and a little external to the incisive fossa; its fibres proceed upward and inward, expanding into a thin aponeurosis which is attached to the fibrocartilage of the nose and is continuous on the bridge of the nose with that of the muscle of the opposite side and with the aponeurosis of the Pyramidalis nasi.

The **Compressor narium minor** is a small muscle attached by one end to the alar cartilage, and by the other to the integument at the end of the nose.

The **Depressor alae nasi** (*m. depressor septi*) is a short radiated muscle *arising* from the incisive fossa of the maxilla; its fibres ascend to be *inserted* into the septum and back part of the ala of the nose. This muscle lies between the mucous membrane and muscular structure of the lip.

Nerves.—All of the muscles of this group are supplied by the facial nerve.

Actions.—The *Pyramidalis nasi* draws down the inner angle of the eyebrows and produces transverse wrinkles over the bridge of the nose. The *Levator labii superioris alaeque nasi* draws upward the upper lip and ala of the nose; its most important action is upon the nose, which it dilates to a considerable extent. The action of this muscle produces a marked influence over the countenance, and it is the principal agent in the expression of contempt and disdain. The two *Dilatatores nasi* enlarge the aperture of the nose. Their action in ordinary breathing is to resist the tendency of the nostrils to close from atmospheric pressure, but in difficult breathing they may be noticed to be in violent action, as well as in some emotions, as anger. The *Depressor alae nasi* is a direct antagonist of the other muscles of the nose, drawing the ala of the nose downward, and thereby constricting the aperture of the nares. The *Compressor naris* depresses the cartilaginous part of the nose and compresses the alae together.

6. The Maxillary Region (Fig. 289).

Levator labii superioris.
Levator anguli oris.

Zygomaticus major.
Zygomaticus minor.

In the BNA term *musculus quadratus labii superioris* three muscles are included. The *caput angulare* is called in this book the *Levator labii superioris alaeque nasi*. The *caput infraorbitale* is called the *Levator labii superioris*. The *caput zygomaticum* is called the *Zygomaticus minor*.¹

The **Levator labii superioris** (*proprius*) is a thin muscle of a quadrilateral form. It arises from the lower margin of the orbit immediately above the infra-orbital foramen, some of its fibres being attached to the maxilla, others to the malar bone; its fibres converge to be *inserted* into the muscular substance of the upper lip.

The **Levator anguli oris** (*m. caninus*) arises from the canine fossa immediately below the infraorbital foramen; its fibres incline downward and a little outward, to be *inserted* into the deep surface of the skin and into the subcutaneous tissue near the angle of the mouth and intermingles with the fibres of the *Zygomaticus major*, the *Depressor anguli oris*, and the *Orbicularis oris*.

The **Zygomaticus major** (*m. zygomaticus*) is a slender fasciculus which arises from the malar bone, in front of the zygomatic suture, and, descending obliquely downward and inward, is *inserted* into the deep surface of the skin and subcutaneous tissue at the outer portion of the upper lip and into the angle of the mouth, where it blends with the fibres of the *Levator anguli oris*, the *Orbicularis oris*, and the *Depressor anguli oris*.

The **Zygomaticus minor**, which is often absent, arises from the malar bone immediately behind the maxillary suture, and, passing downward and inward, is *inserted* internal to the angle of the mouth and is continuous with the *Orbicularis oris* at the outer margin of the *Levator labii superioris*. It lies in front of the *Zygomaticus major*.

Nerves.—This group of muscles is supplied by the facial nerve.

Actions.—The *Levator labii superioris* is the proper elevator of the upper lip, carrying it at the same time a little forward. It assists in forming the *nasolabial ridge* which passes from the side of the nose to the upper lip and gives to the face an expression of sadness. The *Levator anguli oris* raises the angle of the mouth and draws it inward, and assists the *Levator labii superioris* in producing the nasolabial ridge. The *Zygomaticus major* draws the angle of the mouth backward and upward, as in laughing; while the *Zygomaticus minor*, being inserted into the outer part of the upper lip and not into the angle of the mouth, draws it backward, upward, and outward, and thus gives to the face an expression of sadness.

¹ That this grouping is quite artificial and morphologically unwarranted has been shown by McMurrich *American Journal of Anatomy*, vol. iii, Proceedings, p. iii.

7. The Mandibular Region (Fig. 289).

Levator menti.

Depressor labii inferioris.

Depressor anguli oris.

Dissection.—The muscles in this region may be dissected by making a vertical incision through the integument from the margin of the lower lip to the chin; a second incision should then be carried along the margin of the mandible as far as the angle, and the integument carefully removed in the direction shown in Fig. 287.

The **Levator menti** (*m. mentalis*) is a small conical fasciculus placed on the side of the frenum of the lower lip. It *arises* from the mandibular incisive fossa, external to the symphysis of the mandible; its fibres descend to be *inserted* into the integument of the chin.

The **Depressor labii inferioris**, or **Quadratus menti** (*m. quadratus labii inferioris*) (Fig. 295), is a small quadrilateral muscle. It *arises* from the external oblique line of the mandible, between the symphysis and mental foramen, and passes obliquely upward and inward, to be *inserted* into the integument of the lower lip, its fibres blending with the Orbicularis oris and with those of its fellow of the opposite side. It is continuous with the fibres of the Platysma at its origin. This muscle contains much fat intermingled with its fibres.

The **Depressor anguli oris** (*m. triangularis*) (Fig. 289) is triangular in shape, *arising*, by its broad base, from the external oblique line of the mandible, from whence its fibres pass upward, to be *inserted*, by a narrow fasciculus, into the angle of the mouth. It is continuous with the Platysma at its origin and with the Orbicularis oris and Risorius at its insertion, and some of its fibres are directly continuous with those of the Levator anguli oris.¹

Nerves.—This group of muscles is supplied by the facial nerve.

Actions.—The Levator menti raises the lower lip and protrudes it forward, and at the same time wrinkles the integument of the chin, expressing doubt or disdain. The Depressor labii inferioris draws the lower lip directly downward and a little outward, as in the expression of irony. The Depressor anguli oris depresses the angle of the mouth, being the antagonist to the Levator anguli oris and Zygomaticus major; acting with the Levator anguli oris, it will draw the angle of the mouth directly inward.

8. The Buccal Region.

Orbicularis oris.

Buccinator.

Risorius.

Dissection.—The dissection of these muscles may be considerably facilitated by filling the cavity of the mouth with tow, so as to distend the cheeks and lips; the mouth should then be closed by a few stitches and the integument carefully removed from the surface.

The **Orbicularis oris** (Figs. 289 and 295) is not a simple sphincter muscle, like the Orbicularis palpebrarum, but consists of numerous strata of muscle fibres, having different directions, which surround the orifice of the mouth. These fibres are partially derived from the other facial muscles which are inserted into the lips, and are partly fibres proper to the lips themselves. Of the *former*, a considerable number are derived from the Buccinator and form the deeper stratum of the Orbicularis. Some of the Buccinator fibres—namely, those near the middle of the muscle—decussate at the angle of the mouth, those arising from the maxilla passing to the lower lip, and those from the mandible to the

¹ Muscle fibres connecting the two muscles below the chin are occasionally met with; they constitute the *Musculus transversus menti* of His and Waldeyer.

upper lip. Other fibres of the muscle, situated at its upper and lower part, pass across the lips from side to side without decussation. Superficial to this stratum is a *second*, formed by the Levator and Depressor anguli oris, which cross each other at the angle of the mouth, those from the Depressor passing to the upper lip, and those from the Levator to the lower lip, along which they run to be inserted into the skin near the median line. In addition to these there are fibres from the other muscles inserted into the lips—the Levator labii superioris, the Levator labii superioris alaeque nasi, the Zygomatici, and the Depressor labii inferioris; these intermingle with the transverse fibres above described, and have principally an oblique direction. The proper fibres of the lips are oblique, and pass from the under surface of the skin to the mucous membrane through the thickness of the lip. In addition to these are fibres by which the muscle is connected directly with the maxilla and mandible and with the septum of the nose. In the upper lip these consist of two bands, an *inner* and an *outer*, on each side of the nasal plane; the *outer* band (*m. incisivus superior*) arises from the alveolar border of the maxilla, opposite the lateral incisor tooth, and, arching outward on each side, is continuous

FIG. 294.—Plan of the fibres constituting the Orbicularis oris muscle.

at the angle of the mouth with the other muscles inserted into this part. The *inner* band (*m. nasolabialis*) connects the upper lip to the septum of the nose. The interval between the two inner bands corresponds with the depression called the **philtrum** seen on the surface of the skin beneath the septum of the nose. The additional fibres for the lower lip (*m. incisivus inferior*) arise from the mandible, externally to the Levator menti, and arch outward to the angles of the mouth to join the Buccinator and the other muscles attached to this part.

The **Buccinator** (Fig. 295) is a broad, thin muscle, quadrilateral in form, which occupies the interval between the jaws at the side of the face. It arises from the outer surface of the alveolar processes of the maxilla and mandible, corresponding to the three molar teeth, and, behind, from the anterior border of the pterygomandibular ligament, which separates it from the Superior constrictor of the pharynx. The fibres converge toward the angle of the mouth, where the central fibres intersect each other, those from below being continuous with the upper segment of the Orbicularis oris, and those from above with the inferior segment; the highest and lowest fibres continue forward uninterruptedly into the corresponding segment of the lip, without decussation.

Relations.—By its *superficial surface*, behind, with a large mass of fat, the **sucking pad** (*corpus adiposum buccae*), which separates it from the ramus of the mandible, the **Masseter**, and a small portion of the **Temporal** muscle. The sucking pad is much more developed, relatively, in children than in adults. It assists sucking by aiding the cheek to resist atmospheric pressure. The **Buccinator** muscle is in relation, anteriorly, with the **Zygomatici**, **Risorius**, **Levator anguli**

FIG. 295.—Temporal and deep muscles about the mouth. (Testut.)

oris, **Depressor anguli oris**, and the **parotid duct**, which pierces it opposite the second molar tooth of the maxilla; the **facial artery** and **vein** cross it from below upward; it is also crossed by the branches of the **facial** and **buccal nerves**. By its *deep surface* it is in relation with the **buccal glands** and **mucous membrane** of the mouth.

The **pterygomandibular ligament** (*raphe pterygomandibularis*) is a tendinous thickening of the **buccopharyngeal fascia**, attached by one extremity to the apex of the **internal pterygoid plate**, and by the other to the posterior extremity of

the internal oblique line of the mandible. Its *deep surface* corresponds to the cavity of the mouth, and is lined with mucous membrane. Its *superficial surface* is separated from the ramus of the mandible by a quantity of adipose tissue. Its *posterior border* gives attachment to the Superior constrictor of the pharynx; its *anterior border*, to the fibres of the Buccinator.

The **buccopharyngeal fascia** (*fascia buccopharyngea*) is a thin fascia covering the superficial surface of the Buccinator muscle. It is gradually lost in front of the angle of the mouth. Posteriorly, it is continued over the superficial surface of the Constrictor muscles. Its thickened cord-like portion is the stylomandibular ligament.

The **Risorius** (*m. risorius*) (Fig. 289) consists of a narrow bundle of fibres which *arises* in the fascia over the Masseter muscle, and, passing horizontally forward, is *inserted* with the Depressor anguli oris into the subcutaneous and muscular tissue at the angle of the mouth. It is placed superficial to the Platysma, and is broadest at its outer extremity. This muscle varies much in its size and form.

Nerves.—The muscles in this group are all supplied by the facial nerve.

Actions.—The Orbicularis oris in its ordinary action produces the direct closure of the lips; by its deep fibres, assisted by the oblique ones, it closely applies the lips to the alveolar arch. The superficial part, consisting principally of the decussating fibres, brings the lips together and also protrudes them forward. The Buccinators contract and compress the cheeks, so that, during the process of mastication, the food is kept under the immediate pressure of the teeth. When the cheeks have been previously distended with air, the Buccinator muscles expel it from between the lips, as in blowing a trumpet. Hence the name (*buccina*, a trumpet). The Risorius retracts the angles of the mouth, and produces the unpleasant expression which is sometimes seen in tetanus, and is known as *risus sardonicus*, the sardonic laugh.

9. The Temporomandibular Region.

Masseter.

Temporal.

The **masseteric fascia** (*fascia parotideomasseterica*) covers the Masseter muscle. It is firmly connected with this muscle and is derived from the deep cervical fascia. *Above*, this fascia is attached to the lower border of the zygoma, and *behind*, it invests the parotid gland, constituting the **parotid fascia**.

The **Masseter muscle** (*m. masseter*) (Fig. 289) is a short, thick muscle, somewhat quadrilateral in form, consisting of two portions, the superficial and the deep. The **superficial portion**, the larger, *arises* by a thick, tendinous aponeurosis from the malar process of the maxilla, and from the anterior two-thirds of the lower border of the zygomatic arch; its fibres pass downward and backward, to be *inserted* into the angle and lower half of the outer surface of the ramus of the mandible. The **deep portion** is much smaller and more muscular in texture; it *arises* from the posterior third of the lower border and the whole of the deep surface of the zygomatic arch; its fibres pass downward and forward, to be *inserted* into the upper half of the ramus and outer surface of the coronoid process of the mandible. The deep portion of the muscle is partly concealed, in front by the superficial portion; behind, it is covered by the parotid gland. The fibres of the two portions are continuous at their insertion.

Relations.—By its *superficial surface*, with the Zygomatici, the parotid gland, the socia parotidis, the parotid duct, the branches of the facial nerve and the transverse facial vessels, which cross it; the masseteric fascia; the Risorius, Platysma, and the integument. By its *deep surface* it is in relation with the Temporal muscle at its insertion, the ramus of the mandible, the Buccinator and the long buccal nerve, from which it is separated by a mass of fat (sucking pad). The masseteric nerve and artery enter in on its deep surface. Its *posterior margin* is overlapped by the parotid gland. Its *anterior margin*, which projects over the Buccinator muscle, is crossed below by the facial vein.

The **temporal fascia** (*fascia temporalis*) covers the Temporal muscle. It is a strong, fibrous investment, covered, on its superficial surface, by the *Attrahens* and *Attollens aurem* muscles, the aponeurosis of the *Occipitofrontalis*, and by part of the *Orbicularis palpebrarum*. The temporal vessels and the auriculo-temporal nerve cross it from below upward. *Above*, it is a single layer, attached to the entire extent of the upper temporal ridge; but *below*, where it is attached to the zygoma, it consists of two layers, one of which is inserted into the outer, and the other into the inner, border of the zygomatic arch. A small quantity of fat, the orbital branch of the temporal artery, and a filament from the orbital, or temporomalar, branch of the superior maxillary nerve are contained between these two layers. It affords attachment by its deep surface to the superficial fibres of the Temporal muscle.

Dissection.—In order to expose the Temporal muscle, remove the temporal fascia, which may be effected by separating it at its attachment along the upper border of the zygoma and dissecting it upward from the surface of the muscle. The zygomatic arch should then be divided in front at its junction with the malar bone, and behind near the external auditory meatus, and drawn downward with the *Masseter*, which should be detached from its insertion into the ramus and angle of the mandible. The whole extent of the Temporal muscle is then exposed

FIG. 296.—The Temporal muscle, the zygoma and *Masseter* having been removed.

The **Temporal muscle** (*m. temporalis*) (Figs. 295 and 296) is a broad, radiating muscle situated at the side of the head and occupying the entire extent of the temporal fossa. It *arises* from the whole of the temporal fossa except that portion of it which is formed by the malar bone. Its attachment extends from the external angular process of the frontal in front to the mastoid portion of the temporal behind, and from the curved line on the frontal and parietal bones above to the pterygoid ridge on the greater wing of the sphenoid below. It is also attached to the inner surface of the temporal fascia. Its fibres converge as they descend, and terminate in a flat tendon, which is *inserted* into the inner and outer surfaces, apex, and anterior border of the coronoid process and the anterior border of the ramus of the mandible, nearly as far forward as the last molar tooth.

Relations.—By its *superficial surface*, with the integument, the *Attrahens* and *Attollens aurem* muscles, the temporal vessels and nerves, the aponeurosis of the *Occipitofrontalis*, the temporal

fascia, the zygoma, and Masseter; by its *deep surface*, with the temporal fossa, the External pterygoid and part of the Buccinator muscles, the internal maxillary artery and its deep temporal branches, and the deep temporal nerves. *Behind* the tendon are the masseteric vessels and nerve, and in front of it the buccal vessels and nerve. Its *anterior border* is separated from the malar bone by a mass of fat.

Nerves.—Both the Masseter and Temporal muscles are supplied by branches of the inferior maxillary division of the trigeminal nerve.

10. The Pterygomandibular Region (Figs. 297, 298).

External pterygoid.

Internal pterygoid.

Dissection.—The Temporal muscle having been examined, saw through the base of the coronoid process and draw it upward, together with the Temporal muscle, which should be detached from the surface of the temporal fossa. Divide the ramus of the mandible just below the condyle, and also, by a transverse incision extending across the middle, just above the dental foramen; remove the fragment, and the Pterygoid muscles will be exposed.

FIG. 297.—The Pterygoid muscles, the zygomatic arch, and a portion of the ramus of the mandible having been removed.

The **External pterygoid muscle** (*m. pterygoideus externus*) is a short, thick muscle, somewhat conical in form, which extends almost horizontally between the zygomatic fossa and the condyle of the mandible. It *arises* by two heads, separated by a slight interval; the **upper head** *arises* from the inferior surface of the greater wing of the sphenoid and from the pterygoid ridge which separates the zygomatic from the temporal fossa; the **lower head** *arises* from the outer surface of the external pterygoid plate. Its fibres pass horizontally backward and outward, to be *inserted* into a depression in front of the neck of the condyle of the mandible and into the front of the articular disk of the temporomandibular articulation.

Relations.—By its *superficial surface*, with the ramus of the mandible, the internal maxillary artery, which crosses it,¹ the tendon of the Temporal muscle, and the Masseter; by its *deep surface* it rests against the upper part of the Internal pterygoid muscle, the internal lateral ligament, the middle meningeal artery, and inferior maxillary nerve; by its *upper border* it is in relation with the temporal and masseteric branches of the inferior maxillary nerve; by its *lower border* it is in relation with the inferior dental and lingual nerves. Through the interval between the two portions of the muscle, the buccal nerve emerges and the internal maxillary artery passes, when the trunk of this vessel lies on the muscle (Fig. 293).

¹ This is the usual relation, but in many cases the artery will be found below the muscle.

The **Internal pterygoid muscle** (*m. pterygoideus internus*) is a thick, quadrilateral muscle, and resembles the Masseter in form. It arises from the pterygoid fossa, being attached to the inner surface of the external pterygoid plate and to the grooved surface of the tuberosity of the palate bone, and by a second slip from the outer surface of the tuberosities of the palate and maxilla: its fibres pass downward, outward, and backward, to be inserted, by a strong, tendinous lamina, into the lower and back part of the inner side of the ramus and angle of the mandible as high as the dental foramen.

FIG. 298.—The Pterygoid muscles, viewed from behind, the back portion of the skull having been removed. (Testut.)

Relations.—By its *superficial surface*, with the ramus of the mandible, from which it is separated, at its upper part, by the External pterygoid muscle, the internal lateral ligament, the internal maxillary artery, the dental vessels and nerves, and the lingual nerve, and a process of the parotid gland. By its *deep surface*, with the Tensor palati, being separated from the Superior constrictor of the pharynx by a cellular interval.

Nerves.—These muscles are supplied by branches of the inferior maxillary division of the trigeminal nerve.

Actions.—The Temporal, Masseter, and Internal pterygoid *raise* the mandible against the maxillæ with great force. The External pterygoids assist in opening the mouth, but their main action is to *draw forward* the condyles and articular disks so that the mandible is protruded and the inferior incisors are projected in front of the upper; in this action they are assisted by the Internal pterygoids. The mandible is *retracted* by the posterior fibres of the Temporal. If the Internal and External pterygoids of one side act, the corresponding side of the mandible is *drawn forward*, while the opposite condyle remains comparatively fixed, and *lateral movement*, such as occurs during the trituration of the food, takes place.

Surface Form.—The outline of the muscles of the head and face cannot be traced on the surface of the body, except in the case of two of the masticatory muscles. Those of the head

are thin, so that the outline of the bone is perceptible beneath them. Those in the face are small, covered by soft skin, and often by a considerable layer of fat, so that their outline is concealed, but they serve to round off and smooth prominent borders and to fill up what would be otherwise unsightly angular depressions. Thus, the *Orbicularis palpebrarum* rounds off the prominent margin of the orbit, and the *Pyramidalis nasi* fills in the sharp depression beneath the glabella, and thus softens and tones down the abrupt depression which is seen on the unclothed bone. In like manner, the labial muscles, converging to the lips and assisted by the superimposed fat, fill in the sunken hollow of the lower part of the face. Although the muscles of the face are usually described as arising from the bones and inserted into the nose, lips, and corners of the mouth, they have fibres inserted into the skin of the face along their whole extent, so that almost every point of the skin of the face has its muscular fibre to move it; hence it is that when in action the facial muscles produce alterations in the skin-surface, giving rise to the formation of various folds or wrinkles, or otherwise altering the relative position of the parts, so as to produce the varied expressions with which the face is endowed; hence these muscles are termed the *muscles of expression*.¹ The only two muscles in this region which greatly influence surface form are the *Masseter* and the *Temporal*. The *Masseter* is a quadrilateral muscle, which imparts fullness to the hinder part of the cheek. When the muscle is firmly contracted, as when the teeth are clenched, its outline is plainly visible; the anterior border forms a prominent vertical ridge, behind which is a considerable fullness, especially marked at the lower part of the muscle; this fullness is entirely lost when the mouth is opened and the muscle no longer in a state of contraction. The *Temporal* muscle is fan-shaped, and fills the temporal fossa, substituting for it a somewhat convex form, the anterior part of which, on account of the absence of hair over the temple, is more marked than the posterior, and stands out in strong relief when the muscle is in a state of contraction.

MUSCLES AND FASCIÆ OF THE NECK.

The muscles of the neck may be arranged into groups corresponding with the region in which they are situated.

These groups are nine in number:

- | | |
|---------------------------------|-------------------------------|
| 1. Superficial Cervical Region. | 5. Pharyngeal Region. |
| 2. Infrahyoid Region. | 6. Palatal Region. |
| 3. Suprahyoid Region. | 7. Anterior Vertebral Region. |
| 4. Lingual Region. | 8. Lateral Vertebral Region. |
| 9. Muscles of the Larynx. | |

The muscles contained in each of these groups are the following:

1. *Superficial Region.*

Platysma.
Sternomastoid.

2. *Infrahyoid Region.*

Sternohyoid.
Sternothyroid.
Thyrohyoid.
Omohyoid.

3. *Suprahyoid Region.*

Digastric
Stylohyoid.
Mylohyoid.
Geniohyoid.

4. *Lingual Region.*

Extrinsic.	{	Geniohyoglossus.	
		Hyoglossus.	
		Chondroglossus.	
		Styloglossus.	
	Intrinsic.	{	Palatoglossus.
			Superior lingual.
			Inferior lingual.
			Transverse lingual.
			Vertical lingual.

5. *Muscles of the Pharynx.*

Inferior constrictor.
Middle constrictor.
Superior constrictor.
Stylopharyngeus.
Palatopharyngeus.
Salpingopharyngeus.

¹ Consult Darwin, *The Expression of the Emotions in Man and Animals*, and several articles in the *Journal of Anatomy and Physiology*, vols. xiii, xiv, and xxxi.

6. *Muscles of the Soft Palate.*

Levator palati.
Tensor palati.
Azygos uvulae.
Palatoglossus.
Palatopharyngeus.
Salpingopharyngeus.

8. *Muscles of the Lateral Vertebral Region.*

Scalenus anticus.
Scalenus medius.
Scalenus posticus.

7. *Muscles of the Anterior Vertebral Region.*

Rectus capitis anticus major.
Rectus capitis anticus minor.
Rectus capitis lateralis.
Longus colli.

9. *Muscles of the Larynx (Intrinsic).*

Included in the description of the Larynx.

1. **The Superficial Cervical Region.**

Platysma.

Sternomastoid.

Dissection.—A block having been placed at the back of the neck, and the face turned to the side opposite that to be dissected, so as to place the parts upon the stretch, make two transverse incisions, one from the chin, along the margin of the mandible, to the mastoid process, and the other along the upper border of the clavicle. Connect these by an oblique incision made in the course of the Sternomastoid muscle, from the mastoid process to the sternum; the two flaps of integument having been removed in the direction shown in Fig. 287, the superficial fascia will be exposed.

The **superficial cervical fascia** is a thin, aponeurotic lamina which is hardly demonstrable as a separate membrane. It invests the Platysma.

The **Platysma** (*platysma*) (Fig. 289) is a broad, thin plane of muscle fibres situated on the side of the neck. It *arises* by thin, fibrous bands from the fascia covering the upper part of the Pectoral and Deltoid muscles; its fibres pass over the clavicle and proceed obliquely upward and inward along the side of the neck. The anterior fibres interlace, below and behind the symphysis menti, with the fibres of the muscle of the opposite side; the posterior fibres pass over the mandible, some of them are attached to the bone below the external oblique line, others pass on to be *inserted* into the skin and subcutaneous tissue of the lower part of the face, and many of these fibres blend with the muscles about the angle and lower part of the mouth. Sometimes fibres can be traced to the Zygomatic muscles or to the margin of the Orbicularis oris. Beneath the Platysma the external jugular vein may be seen descending in a line from the angle of the mandible to the middle of the clavicle.

Relations.—By its *superficial surface*, with the integument, to which it is united more closely below than above; by its *deep surface*, with the Pectoralis major and Deltoid, and with the clavicle. In the *neck*, with the external and anterior jugular veins, the deep cervical fascia, the superficial branches of the cervical plexus, the Sternomastoid, Sternohyoid, Omohyoid, and Digastric muscles. Behind the Sternomastoid muscle the Platysma covers in the posterior triangle of the neck; on the *face* it is in relation with the parotid gland, the facial artery and vein, and the Masseter and Buccinator muscles.

Nerves.—The lower division of the facial nerve supplies this muscle.

Action.—The Platysma produces a slight wrinkling of the surface of the skin of the neck in an oblique direction, when the entire muscle is brought into action. Its anterior portion, the thickest part of the muscle, depresses the mandible; it also serves to draw down the lower lip and the angle of the mouth on each side, thus being one of the chief agents in the expression

of melancholy. In the pressure upon the bloodvessels of the neck induced by strong inspiratory effort, this muscle draws away the skin and fascia, and by so doing greatly diminishes the pressure on the veins.

The **deep cervical fascia** (*fascia colli*) (Fig. 299) lies under cover of the Platysma muscle and constitutes a complete investment for the neck. It also forms a sheath for the carotid vessels, and, in addition, is prolonged deeply in the shape of certain processes or lamellæ, which come into close relation with the structures situated in front of the vertebral column.

The investing portion of the fascia is attached, *behind*, to the ligamentum nuchæ and to the spine of the seventh cervical vertebra. It forms a thin investment for the Trapezius muscle, at the anterior border of which it is continued forward as a loose areolar layer, which covers the posterior triangle of the neck; thence it passes to the posterior border of the Sternomastoid, where it begins to assume the appearance of a fascial membrane. Along the hinder edge of the Sternomastoid the membrane divides to enclose this muscle, at the anterior edge of which it once more forms a single lamella, which roofs in the anterior triangle of the neck, and, reaching forward to the middle line, is continuous with the corresponding part from the opposite side of the neck. In the middle line of the neck it is attached to the symphysis menti and to the body of the hyoid bone.

Above, the fascia is attached to the superior curved line of the occiput, to the mastoid process of the temporal, and to the whole length of the body of the mandible. Opposite the angle of the mandible the fascia is very strong, and binds the anterior edge of the Sternomastoid firmly to that bone. Between the mandible and the mastoid process it ensheaths the parotid gland—the layer which covers the gland extending upward (*parotid fascia*) to be fixed to the zygomatic arch. The parotid fascia is prolonged forward to cover the Masseter muscle, the *masseteric fascia*. From the layer which passes under the parotid a strong band, the **stylomandibular ligament**, reaches from the styloid process to the angle of the mandible. Three other bands may be defined—the **sphenomandibular**, the **pterygo-mandibular**, and the **pterygospinous ligaments**. The pterygospinous ligament stretches across from the upper half of the posterior free border of the external pterygoid plate to the spinous process of the sphenoid. It occasionally ossifies, producing an adventitious **pterygospinous foramen**, which transmits the branches of the inferior maxillary division of the trigeminal nerve to the muscles of mastication.

Below, the cervical fascia is attached to the acromion process, the clavicle, and to the manubrium sterni. Some little distance above the last-named point, however, it splits into two layers, **superficial** and **deep**. The former is attached to the anterior border of the manubrium, the latter to its posterior border and to the interclavicular ligament. Between these two layers is a slit-like interval, the **suprasternal space** (*spatium suprasternale*). It contains a small quantity of areolar tissue, sometimes a lymph node, the lower portions of the anterior jugular veins and their transverse connecting branch, and also the sternal heads of the Sternomastoid muscles.

The fascia which covers the deep aspect of the Sternomastoid gives off certain important processes, viz.: (1) A process to envelop the tendon of the Omohyoid, and bind it down to the sternum and first costal cartilage. (2) A strong sheath, the **carotid sheath**, for the large vessels of the neck, enclosed within which are the carotid artery, internal jugular vein, the vagus, and descendens hypoglossi nerves. (3) The **prevertebral fascia** (*fascia prævertebralis*), which extends inward behind the carotid vessels, where it assists in forming their sheath, and passes in front of the prevertebral muscles. It thus forms the posterior limit of a fibrous compartment which contains the larynx and trachea, the thyroid gland, and the pharynx

and œsophagus. The prevertebral fascia is fixed above to the base of the skull, while below it is continued into the thorax in front of the Longus colli muscles. Parallel to the carotid vessels and along their inner aspect it gives off a thin lamina, the **buccopharyngeal fascia** (*fascia buccopharyngea*), which closely invests the Constrictor muscles of the pharynx, and is continued forward from the Superior

FIG. 299.—Section of the neck at about the level of the sixth cervical vertebra. Showing the arrangement of the deep cervical fascia.

constrictor on to the Buccinator. The prevertebral fascia is attached to the prevertebral layer by loose connective tissue only, and thus an easily distended space, the **retropharyngeal space** (*spatium retropharyngea*), is found between them. This space is limited above by the base of the skull, while below it extends behind the œsophagus into the thorax, where it is continued into the posterior mediastinum. This fascia is now prolonged downward and outward behind the carotid vessels and in front of the Scalmi muscles, and forms a sheath for the brachial plexus of nerves and for the subclavian vessels in the posterior triangle of the neck, and, continuing under the clavicle as the axillary sheath, is attached to the deep surface of the costocoracoid membrane. Immediately above the clavicle an

areolar space exists between the investing layer and the sheath of the subclavian vessels, and in it are found the lower part of the external jugular vein, the descending clavicular nerves, the suprascapular and transversalis colli vessels, and the posterior belly of the Omohyoid muscle. This space extends downward behind the clavicle, and is limited below by the fusion of the costocoracoid membrane with the anterior wall of the axillary sheath. (4) The **pretracheal fascia**, which extends inward in front of the carotid vessels, and assists in forming the carotid sheath. It is further continued behind the Depressor muscles of the hyoid bone, and, after enveloping the thyroid body, is prolonged in front of the trachea to meet the corresponding layer of the opposite side. Above, it is fixed to the hyoid bone, while below it is carried downward in front of the trachea and large vessels at the root of the neck, and ultimately blends with the fibrous pericardium. This layer is fused on either side with the prevertebral layer, with which it completes the compartment containing the larynx and trachea, the thyroid gland, the pharynx and œsophagus.

Applied Anatomy.—The cervical fascia is of considerable importance from a surgical point of view. As will be seen from the foregoing description, it may be divided into three layers (1) A superficial layer; (2) a layer passing in front of the trachea, and forming with the superficial layer a sheath for the Depressors of the hyoid bone; (3) a prevertebral layer passing in front of the bodies of the cervical vertebræ, and forming with the second layer a space in which are contained the trachea, œsophagus, etc. The superficial layer forms a complete investment for the neck. It is attached behind to the ligamentum nuchæ and the spine of the seventh cervical vertebra; above, it is attached to the external occipital protuberance, to the superior curved line of the occiput, to the mastoid process, to the zygoma and the mandible; below, it is attached to the manubrium sterni, the clavicle, the acromion process, and the spine of the scapula; in front it blends with the fascia of the opposite side. This layer opposes the extension of *abscesses* or new growths toward the surface, and pus forming beneath it has a tendency to extend laterally. If pus is in the posterior triangle, it might extend backward under the Trapezius, forward under the Sternomastoid, or downward under the clavicle for some distance, until stopped by the junction of the cervical fascia to the costocoracoid membrane. If the pus is contained in the anterior triangle, it might find its way into the anterior mediastinum, being situated in front of the layer of fascia which passes down into the thorax to become continuous with the pericardium; but owing to the lesser density and thickness of the fascia in this situation it more frequently finds its way through it and points above the sternum. The second layer of fascia is connected above with the hyoid bone. It passes down beneath the Depressors and in front of the thyroid body and trachea to become continuous with the fibrous layer of the pericardium. Laterally it invests the great vessels of the neck and is connected with the superficial layer beneath the Sternomastoid. Pus forming beneath this layer would in all probability find its way into the posterior mediastinum. The third layer (the prevertebral fascia) is connected above to the base of the skull. Pus forming beneath this layer, in cases, for instance, of caries of the bodies of the cervical vertebræ, might extend toward the posterior and lateral part of the neck and point in this situation, or might perforate this layer of fascia and the pharyngeal fascia and point into the pharynx (*retropharyngeal abscess*).

In cases of *cut throat* the cervical fascia is of considerable importance. When the wound involves only the superficial layer the injury is usually trivial, the only special danger being injury to the external jugular vein, and the only special complication being diffuse cellulitis. But where the second of the two layers has been opened up, and where important structures may have been injured, serious results may ensue.

The **Sternomastoid** (*m. sternocleidomastoideus*) (Fig. 300) is a large, thick muscle, which passes obliquely across the side of the neck, being enclosed between two layers of the deep cervical fascia. It is thick and narrow at its central part, but is broader and thinner at each extremity. It *arises*, by two heads, from the sternum and clavicle. The **sternal portion** is a rounded fasciculus, tendinous in front, fleshy behind, which *arises* from the upper and anterior part of the first piece of the sternum, and is directed upward, outward, and backward. The **clavicular portion** *arises* from the inner third of the superior border and anterior surface of the clavicle, being composed of fleshy and aponeurotic fibres; it is directed almost vertically upward. These two portions are separated from each

other, at their origin, by a triangular cellular interval, but become *gradually* blended, below the middle of the neck, into a thick, rounded muscle, which is *inserted*, by a strong tendon, into the outer surface of the mastoid process of the temporal bone, from its apex to its superior border, and by a thin aponeurosis into the outer half of the superior curved line of the occipital bone. The Sternomastoid varies much in its extent of attachment to the clavicle; in one case the clavicular may be as narrow as the sternal portion; in another, the former, may be as much as three inches in breadth. When the clavicular origin is broad, it is occasionally subdivided into numerous slips separated by narrow intervals. More rarely, the corresponding margins of the Sternomastoid and Trapezius have been found in contact.

FIG. 300.—Muscles of the neck and boundaries of the triangles.

Triangles of the Neck.—The Sternomastoid muscle divides the quadrilateral area of the side of the neck into two triangles, an anterior and a posterior. The boundaries of the **anterior triangle** are, in *front*, the median line of the neck; *above*, the lower border of the body of the mandible, and an imaginary line drawn from the angle of the mandible to the mastoid process; *behind*, the anterior border of the Sternomastoid muscle. The *apex* of the triangle is at the upper border of the sternum. The boundaries of the **posterior triangle** are, in *front*, the posterior border of the Sternomastoid; *below*, the middle third of the clavicle; *behind*, the anterior margin of the Trapezius.¹ The *apex* corresponds with the meeting of the Sternomastoid and Trapezius on the occipital bone.

Relations.—By its *superficial surface*, with the integument and Platysma, from which it is separated by the external jugular vein, some of the superficial branches of the cervical plexus, and the superficial layer of the deep cervical fascia. By its *deep surface* it is in relation with the Sternoclavicular articulation; a process of the deep cervical fascia; the Sternohyoid, Sternothyroid, Omohyoid, posterior belly of the Digastric, Levator anguli scapulae, Splenius and Scaleri muscles; common carotid artery, internal jugular vein, commencement of the internal

¹ The anatomy of these triangles will be more exactly described with that of the vessels of the neck.

and external carotid arteries, the occipital, subclavian, transversalis colli, and suprascapular arteries and veins; the phrenic, vagus, hypoglossal, descendens and communicans hypoglossi nerves; the spinal accessory nerve, which pierces its upper third; the cervical plexus, parts of the thyroid and parotid glands, and deep lymph nodes.

Nerves.—The Sternomastoid is supplied by the spinal accessory nerve and deep branches of the cervical plexus.

Actions.—When only one Sternomastoid muscle acts, it draws the head toward the shoulder of the same side, assisted by the Splenius and the Obliquus capitis inferior of the opposite side. At the same time it rotates the head so as to carry the face toward the opposite side. When the two muscles act together they flex the head upon the neck. If the head is fixed, the two muscles assist in elevating the thorax in forced inspiration.

Applied Anatomy.—The applied anatomy of the Sternomastoid muscle is of importance chiefly in connection with the deformity known as *wry-neck* (*torticollis*). Wry-neck may be either acquired, congenital, or spasmodic. The *acquired* may be caused by acute glandular enlargement, cellulitis of the neck, myositis of the Sternomastoid, or cervical caries. The *congenital* variety is due to injury of the Sternomastoid during birth, which probably causes a subsequent chronic fibrous myositis (Mikulicz). This is best remedied by making an open horizontal incision over the origin of the muscle and exposing it. A director is then passed underneath and the muscle clearly divided, making sure that any tense bands of fascia are thoroughly divided. *Spasmodic torticollis* is a condition of adult life. It is marked by clonic or tonic spasm, first of the Sternomastoid, then of many of the other neck muscles. It is thought to be a disease of the central nerve system.

2. The Infrahyoid Region (Figs. 300, 301).

DEPRESSORS OF THE HYOID BONE AND LARYNX.

Sternohyoid.
Sternothyroid.

Thyrohyoid.
Omohyoid.

Dissection.—The muscles in this region may be exposed by removing the deep fascia from the front of the neck. In order to see the entire extent of the Omohyoid it is necessary to divide the Sternomastoid at its centre, and turn its ends aside, and to detach the Trapezius from the clavicle and scapula. This, however, should not be done until the Trapezius has been dissected.

The **Sternohyoid** (*m. sternohyoideus*) is a thin, narrow, ribbon-like muscle, which *arises* from the inner extremity of the clavicle, the posterior sternoclavicular ligament, and the upper and posterior part of the first piece of the sternum; passing upward and inward, it is *inserted*, by short, tendinous fibres, into the lower border of the body of the hyoid bone. This muscle is separated, below, from its fellow by a considerable interval; but the two muscles come into contact with each other in the middle of their course, and from this upward lie side by side. It sometimes presents, immediately above its origin, a transverse tendinous intersection, like those in the Rectus abdominis. As a rule, two bursæ (*bursae sternohyoidii*) lie between the cricothyroid membrane and the Sternohyoid muscle.

Relations.—By its *superficial surface*, *below*, with the sternum, the sternal end of the clavicle, and the Sternomastoid; and *above*, with the Platysma and deep cervical fascia; by its *deep surface*, with the Sternothyroid, Cricothyroid, and Thyrohyoid muscles, the thyroid gland, the superior thyroid vessels, the thyroid cartilage, the cricothyroid and thyrohyoid membranes.

The **Sternothyroid** (*m. sternothyreoideus*) is situated beneath the preceding muscle, but is shorter and wider than it. It *arises* from the posterior surface of the first piece of the sternum, below the origin of the Sternohyoid, and from the edge of the cartilage of the first rib, occasionally of the second rib also, and is *inserted* into the oblique line on the side of the ala of the thyroid cartilage. This muscle is in close contact with its fellow at the lower part of the neck, and is occa-

sionally traversed by a transverse or oblique tendinous intersection, like those in the Rectus abdominis.

Relations.—By its *superficial surface*, with the Sternohyoid, Omohyoid, and Sternomastoid; by its *deep surface*, from below upward, with the trachea, innominate veins, common carotid (and on the right side the innominate artery), the thyroid gland and its vessels, and the lower part of the larynx and pharynx. The inferior thyroid vein lies along its *inner border*, a relation which it is important to remember in the operation of tracheotomy. On the left side the deep surface of the muscle is in relation to the œsophagus.

The **Thyrohyoid** (*m. thyrohyoideus*) is a small, quadrilateral muscle appearing like a continuation of the Sternohyoid. It *arises* from the oblique line on the side of the thyroid cartilage, and passes vertically upward to be *inserted* into the lower border of the body and greater cornu of the hyoid bone.

Relations.—By its *superficial surface*, with the Sternohyoid and Omohyoid muscles; by its *deep surface*, with the thyroid cartilage, the thyrohyoid membrane, and the superior laryngeal vessels and nerve.

FIG. 301.—Muscles of the neck. Anterior view.

The **Omohyoid** (*m. omohyoideus*) passes across the side of the neck, from the scapula to the hyoid bone. It consists of two fleshy bellies, united by a central tendon. It *arises* from the upper border of the scapula, and occasionally from the transverse ligament which crosses the suprascapular notch, its extent of attachment to the scapula varying from one-sixth of an inch to an inch. From this origin the **posterior belly** (*venter inferior*) forms a flat, narrow fasciculus, which inclines forward and slightly upward across the lower part of the neck, behind the Sternomastoid muscle, where it becomes tendinous; it then changes its direction, forming an obtuse angle, and terminates in the **anterior belly** (*venter superior*), which passes almost vertically upward, close to the outer border of the Sternohyoid, to be *inserted* into the lower border of the body of the hyoid bone, just external to

the insertion of the Sternohyoid. The central tendon of this muscle, which varies much in length and form, is held in position by a process of the deep cervical fascia, which includes it in a sheath. This process is prolonged down, to be attached to the clavicle and first rib. It is by this means that the angular form of the muscle is maintained.

The posterior belly of the Omohyoid divides the posterior triangle of the neck into an upper or **occipital**, and a lower or **subclavian triangle**, while its anterior belly divides the anterior triangle of the neck into an upper or **carotid**, and a lower or **muscular triangle**.

Relations.—By its *superficial surface*, with the Trapezius, the Sternomastoid, deep cervical fascia, Platysma, and integument; by its *deep surface*, with the Scaleri muscles, phrenic nerve, lower cervical nerves which go to form the brachial plexus, the suprascapular vessels and nerve, sheath of the common carotid artery and internal jugular vein, the Sternothyroid and Thyrohyoid muscles.

Nerves.—The Depressors of the hyoid bone are supplied by branches from the *ansa cervicalis* formed by the first three cervical nerves. The branch to the Thyrohyoid accompanies the hypoglossal nerve in a common sheath, but leaves the hypoglossal trunk as it approaches the hyoid bone.

Actions.—These muscles depress the larynx and hyoid bone, after they have been drawn up with the pharynx in the act of deglutition. The Omohyoid muscles not only depress the hyoid bone, but carry it backward and to one side. This bone is concerned especially in prolonged inspiratory efforts; for by rendering the lower part of the cervical fascia tense it lessens the inward suction of the soft parts, which would otherwise compress the great vessels and the apices of the lungs. This action is synergistic with that of the Platysma. The Thyrohyoid may act as an elevator of the thyroid cartilage when the hyoid bone ascends, drawing upward the thyroid cartilage, behind this bone. The Sternothyroid acts as a depressor of the thyroid cartilage.

3. The Suprahyoid Region (Figs. 300, 301).

ELEVATORS OF THE HYOID BONE—DEPRESSORS OF THE MANDIBLE.

Digastric.
Stylohyoid.

Mylohyoid.
Geniohyoid.

Dissection.—To dissect these muscles a block should be placed beneath the back of the neck, and the head drawn backward and retained in that position. On the removal of the deep fascia the muscles are at once exposed.

The **Digastric** (*m. digastricus*) consists of two fleshy bellies united by an intermediate, rounded tendon. It is a small muscle, situated below the side of the body of the mandible, and extending, in a curved form, from the side of the head to the symphysis of the mandible. The **posterior belly** (*venter posterior*), longer than the anterior, *arises* from the digastric groove on the inner side of the mastoid process of the temporal bone, and passes downward, forward, and inward. The **anterior belly** (*venter anterior*) *arises* from a depression on the inner side of the lower border of the mandible, close to the symphysis, and passes downward and backward. The two bellies terminate in the central tendon which perforates the Stylohyoid, and is held in connection with the side of the body and the greater cornu of the hyoid bone by a fibrous loop, lined with a synovial membrane. A broad aponeurotic layer is given off from the tendon of the Digastric on each side, which is attached to the body and greater cornu of the hyoid bone; this is termed the **suprahyoid aponeurosis**. It forms a strong layer of fascia between the anterior portions of the two muscles, and a firm investment for the other muscles of the suprahyoid region which lie deeper.

The Digastric muscle divides the anterior superior triangle of the neck into two smaller triangles; the **submaxillary triangle**, bounded, *above*, by the lower border of the body of the mandible, and a line drawn from its angle to the mastoid process; *below*, by the posterior

belly of the Digastric and the Stylohyoid muscles; in *front*, by the middle line of the neck and the anterior belly of the Digastric; the **carotid triangle** bounded *above* by the posterior belly of the Digastric, *behind* by the Sternomastoid, *below* by the anterior belly of the Omohyoid; the **suprahyoid** or **submental triangle**, bounded *externally* by the anterior belly of the Digastric, *internally* by the mesal line of the neck from the hyoid bone to the symphysis menti, and *inferiorly* by the body of the hyoid bone.

Relations.—By its *superficial surface*, with the mastoid process, the Platysma, Sternomastoid, part of the Splenius, Trachelomastoid, and Stylohyoid muscles, and the parotid gland. By its *deep surface*, the anterior belly lies on the Mylohyoid; the posterior belly on the Styloglossus, Stylopharyngeus, and Hyoglossus muscles, the external carotid artery and its occipital, lingual, facial, and ascending pharyngeal branches, the internal carotid artery, internal jugular vein, and hypoglossal nerve.

The **Stylohyoid** (*m. stylohyoideus*) is a small, slender muscle, lying in front of and above the posterior belly of the Digastric. It *arises* from the back and outer surface of the styloid process of the temporal bone, near the base; and, passing downward and forward, is *inserted* into the body of the hyoid bone, just at its junction with the greater cornu, and immediately above the Omohyoid. This muscle is perforated, near its insertion, by the tendon of the Digastric.

FIG. 302.—Mylohyoid muscle. (Poirier and Charpy.)

Relations.—By its *superficial surface*, *above*, with the parotid gland and deep cervical fascia; *below*, this muscle is superficial, being situated immediately beneath the deep cervical fascia. By its *deep surface*, with the posterior belly of the Digastric, the external carotid artery, with its lingual and facial branches, the Hyoglossus muscle, and the hypoglossal nerve.

The Stylohyoid Ligament (*ligamentum stylohyoideus*).—In connection with the Stylohyoid muscle may be described a ligamentous band, the **stylohyoid ligament**. It is a fibrous cord, often containing a little cartilage in its centre, which continues the styloid process down to the hyoid bone, being attached to the tip of the former and to the lesser cornu of the latter. It is often more or less ossified, and in many animals forms a distinct bone, the *epihyal*.

The **Mylohyoid** (*m. mylohyoideus*) (Fig. 302) is a flat, triangular muscle, situated immediately beneath the anterior belly of the Digastric, and forming, with its fellow of the opposite side, a muscular floor for the cavity of the mouth. It *arises* from the whole length of the mylohyoid ridge of the mandible, extending from the symphysis in front to the last molar tooth behind. The posterior fibres pass inward and slightly downward, to be *inserted* into the body of the hyoid

bone. The middle and anterior fibres are *inserted* into a median fibrous raphé, extending from the symphysis of the mandible to the hyoid bone, where they join at an angle with the fibres of the opposite muscle. The median raphé is sometimes wanting; the muscle fibres of the two sides are then directly continuous with one another.

Relations.—By its *superficial surface*, with the Platysma, the anterior belly of the Digastric, the suprahyoid aponeurosis, the submaxillary gland, submental vessels, and mylohyoid vessels and nerve; by its *deep surface*, with the Geniohyoid, part of the Hyoglossus and Styloglossus muscles, the hypoglossal and lingual nerves, the submaxillary ganglion, the sublingual gland, the deep portion of the submaxillary gland and duct; the sublingual and ranine vessels, and the buccal mucous membrane.

FIG. 303.—Muscles of the tongue. Left side.

Dissection.—The Mylohyoid should now be removed, in order to expose the muscles which lie beneath; this is effected by reflecting it from its attachments to the hyoid bone and mandible, and separating it by a vertical incision from its fellow of the opposite side.

The **Geniohyoid** (*m. geniohyoideus*) (Fig. 303) is a narrow, slender muscle, situated immediately beneath¹ the inner border of the Mylohyoid. It *arises* from the inferior genial tubercle on the inner side of the symphysis of the mandible, and passes downward and backward, to be *inserted* into the anterior surface of the body of the hyoid bone. This muscle lies in close contact with its fellow of the opposite side, and increases slightly in breadth as it descends.

Relations.—It is covered by the Mylohyoid and lies along the lower border of the Geniohyoglossus.

¹ This refers to the depth of the muscles from the skin in the order of dissection. In the erect position of the body the Geniohyoid is above the Mylohyoid.

Nerves.—The anterior belly of the Digastric is supplied by the mylohyoid branch of the inferior dental; its posterior belly, by the facial; the Stylohyoid is supplied by the facial; the Mylohyoid, by the mylohyoid branch of the inferior dental; the Geniohyoid, by a branch from the ansa cervicalis which accompanies the hypoglossal in a common sheath.

Actions.—This group of muscles performs two very important actions. They raise the hyoid bone, and with it the base of the tongue, during the act of deglutition; or, when the hyoid bone is fixed by its Depressors and those of the larynx, they depress the mandible. During the first act of deglutition, when the mass is being driven from the mouth into the pharynx, the hyoid bone, and with it the tongue, is carried upward and forward by the anterior belly of the Digastric, the Mylohyoid, and Geniohyoid muscles. In the second act, when the mass is passing through the pharynx, the direct elevation of the hyoid bone takes place by the combined action of all the muscles; and after the food has passed, the hyoid bone is carried upward and backward by the posterior belly of the Digastric and Stylohyoid muscles, which assist in preventing the return of the bolus into the mouth.

4. The Lingual Region (Figs. 303, 304).

Geniohyoglossus.
Hyoglossus.

Styloglossus.
Palatoglossus.¹

Chondroglossus.

Dissection.—After completing the dissection of the preceding muscles, saw through the mandible just external to the symphysis. Then draw the tongue forward, and attach it, by a stitch, to the nose; when its muscles, which are thus put on a stretch, may be examined.

The **Geniohyoglossus** (*m. genioglossus*) has received its name from its triple attachment to the mandible, hyoid bone, and tongue. It is a flat, triangular muscle, placed vertically on either side of the middle line, its apex corresponding with its point of attachment to the mandible, its base with its insertion into the tongue and hyoid bone. It *arises* by a short tendon from the superior genial tubercle on the inner side of the symphysis of the mandible, immediately above the Geniohyoid; from this point the muscle spreads out in a fan-like form, a few of the inferior fibres passing downward, to be *attached* by a thin aponeurosis into the upper part of the body of the hyoid bone, a few fibres passing between the Hyoglossus and Chondroglossus to blend with the Constrictor muscles of the pharynx; the middle fibres passing backward, and the superior ones upward and forward, to enter the whole length of the under surface of the tongue, from the base to the apex. The two muscles lie on either side of the median plane; behind they are quite distinct from each other, and are separated at their insertion into the under surface of the tongue by a tendinous raphé, which extends through the middle of the organ. In front the two muscles are more or less blended; distinct fasciculi are to be seen passing off from one muscle, crossing the middle line, and intersecting with bundles of fibres derived from the muscle on the other side.

Relations.—By its *deep surface* this muscle is in contact with its fellow of the opposite side; by its *superficial surface*, with the Inferior lingualis, the Hyoglossus, the lingual artery and hypoglossal nerve, the lingual nerve, and sublingual gland; by its *upper border*, with the mucous membrane of the floor of the mouth (*frenum linguae*); by its *lower border* with the Geniohyoid.

The **Hyoglossus** (*m. hyoglossus*) is a thin, flat, quadrilateral muscle which *arises* from the side of the body and whole length of the greater cornu of the hyoid bone, and passes almost vertically upward to enter the side of the tongue, between the Styloglossus and Lingualis. The fibres of this muscle which arise

¹ The Palatoglossus, or *constrictor isthmi faucium*, although one of the muscles of the tongue which serves to draw the base of that organ upward during the act of deglutition, is more nearly associated, both in situation and function, with the soft palate. It will consequently be described with the group of Palatal muscles.

from the body are directed upward and backward, overlapping those arising from the greater cornu, which are directed upward and forward.

Relations.—By its *superficial surface*, with the Digastric, the Stylohyoid, Styloglossus, and Mylohyoid muscles, the submaxillary ganglion, the lingual and hypoglossal nerves, the submaxillary duct, the ranine vein, the sublingual gland, and the deep portion of the submaxillary gland. By its *deep surface*, with the Stylohyoid ligament, the Geniohyoglossus, Lingualis, and Middle constrictor, the lingual vessels, and the glossopharyngeal nerve.

The **Chondroglossus** (*m. chondroglossus*) is a distinct muscular slip, though it is sometimes described as a part of the Hyoglossus, from which, however, it is separated by the fibres of the Geniohyoglossus, which pass to the side of the pharynx. It is about three-quarters to an inch in length; it *arises* from the inner side and base of the lesser cornu and contiguous portion of the body of the hyoid bone, and passes directly upward to blend with the Intrinsic muscle fibres of the tongue, between the Hyoglossus and Geniohyoglossus.

The **Styloglossus** (*m. styloglossus*), the shortest and smallest of the three styloid muscles, *arises* from the anterior and outer side of the styloid process, near the apex, and from the stylomandibular ligament, to which its fibres, in most cases, are attached by a thin aponeurosis. Passing downward and forward between the internal and external carotid arteries, and becoming nearly horizontal in its direction, this muscle divides upon the side of the tongue into two portions—one longitudinal, which enters the

CUT EDGE OF SUPERIOR LINGUALIS.

FIG. 304.—Muscles on the dorsum of the tongue.

(Altered from Krause.)

side of the tongue near its dorsal surface and blends with the fibres of the Lingualis in front of the Hyoglossus; the other oblique, which overlaps the Hyoglossus muscle and decussates with its fibres.

Relations.—By its *superficial surface*, from above downward, with the parotid gland, the Internal pterygoid muscle, the lingual nerve, and the mucous membrane of the mouth; by its *deep surface*, with the tonsil, the Superior constrictor, and the Hyoglossus muscle.

Nerves.—The muscles of this group are supplied by the hypoglossal nerve.

The Muscle Substance of the Tongue (Figs. 304 and 305).—The muscle fibres of the tongue run in various directions. These fibres are divided into two sets—Extrinsic and Intrinsic. The **Extrinsic muscles** of the tongue are those which have their origin *external to*, and only their terminal fibres contained *within*, the substance of the organ. They are: the Styloglossus, the Hyoglossus, the Palatoglossus, the Geniohyoglossus, and part of the Superior constrictor of the pharynx (Pharyngoglossus). The **Intrinsic muscles** are those which are contained entirely *within* the tongue, and which form the greater part of its muscular structure.

The tongue consists of symmetrical halves separated from each other in the middle line by a **fibrous septum** (*septum lingue*). Each half is composed of muscle fibres arranged in various directions, containing much interposed fat, and supplied by vessels and nerves. Immediately beneath the mucous membrane is a *submucous fibrous layer*, into which the muscle fibres which terminate in this stratum of the tongue are inserted. Upon removing this, with the mucous membrane, the *first stratum* of muscle fibres is exposed. This belongs to the group of Intrinsic muscles, and has been named the **Superior lingualis** (*m. longitudinalis superior*). It consists of a thin layer of oblique and longitudinal fibres which *arise* from the submucous fibrous layer, close to the epiglottis, and from the fibrous septum, and which pass forward and outward to the edges of the tongue. Between its fibres pass some vertical fibres derived from the Geniohyoglossus and from the vertical Intrinsic muscle, which will be described later on.

Beneath this layer is the *second stratum* of muscle fibres, derived principally from the Extrinsic muscles. In front this stratum is formed by the fibres derived from the Styloglossus, which run along the side of the tongue and which in turn send out two sets of fibres. The *first* of these two latter sets of fibres extends over the dorsum and runs obliquely forward and inward to the middle line. The *second* set of fibres goes on to the under surface of the sides of the anterior part of the tongue, and runs between the fibres of the Hyoglossus muscle forward and inward to the middle line. *Behind* this layer of fibres, derived from the Styloglossus, are fibres derived from the Hyoglossus, assisted by some few fibres of the Palatoglossus. The Hyoglossus, entering the side of the under surface of the tongue, between the Styloglossus and Inferior lingualis, passes around its margin and spreads out into a layer on the dorsum, which occupies the middle third of the organ, and runs almost transversely inward to the septum. It is reinforced by some fibres from the Palatoglossus; other fibres of this muscle pass more deeply and intermingle with the next layer. The posterior part of the second layer of the muscle fibres of the tongue is derived from those fibres of the Hyoglossus which arise from the lesser cornu of the hyoid bone, and are here described as a separate muscle—the **Ohondroglossus**. The fibres of this muscle are arranged in a fan-shaped manner, and spread out over the posterior third of the tongue.

Beneath this layer is the *third layer*, the great mass of Intrinsic muscles of the tongue, which is intersected at right angles by the terminal fibres of one of the Extrinsic muscles—the Geniohyoglossus. This portion of the tongue is paler in color and softer in texture than that already described, and is sometimes designated the medullary portion in contradistinction to the firmer superficial part, which is termed the cortical portion. The medullary portion consists largely of transverse fibres, the Transverse lingualis, and of vertical fibres, the Vertical lingualis. The **Transverse lingualis** (*m. transversus lingue*) forms the largest portion of the third layer of muscle fibres of the tongue. The fibres *arise* from the median septum, and pass outward to be *inserted* into the submucous fibrous layer at the sides of the tongue. Intermingled with these transverse intrinsic fibres are transverse extrinsic fibres derived from the Palatoglossus and the Superior constrictor of the pharynx. These transverse extrinsic fibres, however, run in the opposite direction, passing inward toward the septum. Intersecting the transverse fibres are a large number of vertical fibres derived partly from the Geniohyoglossus and partly from intrinsic fibres, the Vertical lingualis. The fibres derived from the Geniohyoglossus enter the under surface of the tongue on each side of the median septum from base to apex. They ascend in a radiating manner to the dorsum, being inserted into the submucous fibrous layer covering the tongue on each side of the middle line. The **Vertical lingualis** (*m. verticalis lingue*) is found only at the borders of the forepart of the tongue, external to the fibres of the Geniohyoglossus. Its fibres extend from the upper to the under surface of the organ, and decussate with the fibres of the other muscles, and especially with those of the Transverse lingualis.

The *fourth layer* of muscle fibres of the tongue consists partly of extrinsic fibres derived from the Styloglossus, and partly of intrinsic fibres, the Inferior lingualis. At the sides of the under surface of the organ are some fibres derived from the Styloglossus, which, as it runs forward at the side of the tongue, gives off fibres which, passing forward and inward between the fibres of the Hyoglossus, form an inferior oblique stratum which joins in front with the anterior fibres of the Inferior lingualis. The **Inferior lingualis** (*m. longitudinalis inferior*) is a longitudinal band, situated on the under surface of the tongue, and extending from the base to the apex of the organ. Behind, some of its fibres are connected with the body of the hyoid bone. It lies between the Hyoglossus and the Geniohyoglossus, and in front of the Hyoglossus it enters into relation with the Styloglossus, with the fibres of which it blends. It is in relation by its under surface with the ranine artery.

Applied Anatomy.—The fibrous septum which exists between the two halves of the tongue is almost complete, so that the anastomosis between the two lingual arteries is not very free, a fact often illustrated by injecting one-half of the tongue with colored gelatin, while the other half is left uninjected or may be injected with gelatine of a different color.

This is a point of considerable importance in connection with removal of one-half of the tongue for cancer, an operation which is now frequently resorted to when the disease is strictly confined to one side of the anterior portion of the tongue. If the mucous membrane is divided longitudinally exactly in the middle line, the tongue can be split into halves along the median raphe without any appreciable hemorrhage, and the diseased half can then be removed.

Actions.—The movements of the tongue, although numerous and complicated, may be understood by carefully considering the direction of the fibres of its muscles. The Geniohyoglossi muscles, by means of their posterior fibres, draw the base of the tongue forward, so as to protrude the apex from the mouth. The anterior fibres draw the tongue back into the mouth. The whole length of these two muscles, acting along the middle line of the tongue, draw it downward, so as to make it concave from side to side, forming a channel along which fluids may pass toward the pharynx, as in sucking. The Hyoglossi muscles depress the tongue and draw down its sides, so as to render it convex from side to side. The Styloglossi muscles draw the tongue upward and backward. The Palatoglossi muscles draw the base of the tongue upward. With regard to the Intrinsic muscles, both the Superior and Inferior lingualis tend to shorten the tongue, but the former, in addition, turn the tip and sides upward so as to render the dorsum concave, while the latter pull the tip downward and cause the dorsum to become convex. The Transverse lingualis narrows and elongates the tongue, and the Vertical lingualis flattens and broadens it. The complex arrangement of the muscle fibres of the tongue, and the various directions in which they run, give to this organ the power of assuming the various forms necessary for the enunciation of the different consonantal sounds.

5. The Pharyngeal Region (Figs. 306, 307).

Inferior constrictor.

Middle constrictor.

Palatopharyngeus.

Salpingopharyngeus. } (See next section.)

Superior constrictor.

Stylopharyngeus.

Dissection (Fig. 306).—In order to examine the muscles of the pharynx, cut through the trachea and œsophagus just above the sternum, and draw them upward by dividing the loose areolar tissue connecting the pharynx with the front of the vertebral column. The parts being drawn well forward, apply the edge of the saw immediately behind the styloid processes, and saw the base of the skull through from below upward. The pharynx and mouth should then be stuffed with tow, in order to distend its cavity and render the muscles tense and easier of dissection.

The **Inferior constrictor** (*m. constrictor pharyngis inferior*), the most superficial and thickest of the three Constrictors, *arises* from the side of the cricoid cartilages, in the interval between the Cricothyroid muscle in front and the articular facet for the thyroid cartilage behind; from the oblique line on the side of the ala of the thyroid cartilage, the cartilaginous surface behind it, nearly as far as its posterior border, and from the inferior cornu. From these origins the fibres spread backward and inward, to be *inserted* into the fibrous raphe in the posterior median line of the pharynx. The inferior fibres are horizontal, and continuous with the fibres of the œsophagus; the rest ascend, increasing in obliquity, and overlap the Middle constrictor.

Relations.—The Inferior Constrictor is covered by a thin membrane which surrounds the entire pharynx, the **buccopharyngeal fascia** (*fascia buccopharyngea*). *Behind*, this fascia is in relation with the vertebral column and the prevertebral fascia and muscles; *laterally*, with the thyroid gland, the common carotid artery, and the Sternothyroid muscle; by its *deep surface*, with the Middle constrictor, the Stylopharyngeus, Palatopharyngeus, the fibrous coat and mucous membrane of the pharynx. The internal laryngeal nerve and the laryngeal branch of the superior thyroid artery pass near the upper border, and the inferior, or recurrent laryngeal nerve, and the laryngeal branch of the inferior thyroid artery, beneath the lower border of this muscle, previous to their entering the larynx.

The **Middle constrictor** (*m. constrictor pharyngis medius*) is a flattened, fan-shaped muscle, smaller than the preceding. It arises from the whole length of the upper border of the greater cornu of the hyoid bone, from the lesser cornu, and from the stylohyoid ligament. The fibres diverge from their origin, the lower ones descending beneath the Inferior constrictor, the middle fibres passing transversely, and the upper fibres ascending and overlapping the Superior constrictor. The muscle is inserted into the posterior median fibrous raphé, blending in the middle line with its fellow of the opposite side.

Relations.—Between this muscle and the Superior constrictor are the glossopharyngeal nerve, the Stylopharyngeus muscle and the stylohyoid ligament; and between it and the Inferior constrictor is the superior laryngeal nerve. *Behind*, the Middle constrictor lies on the vertebral column, the Longus colli, and the Rectus capitis anticus major. *On each side* it is in relation with the carotid vessels, the pharyngeal plexus, and some lymph nodes. Near its origin it is covered by the Hyoglossus, the lingual vessels being placed between the two muscles. It lies *upon* the Superior constrictor, the Stylopharyngeus, the Palatopharyngeus, the fibrous coat, and the mucous membrane of the pharynx.

FIG. 306.—Muscles of the pharynx. External view.

spine on the basilar process of the occipital bone.¹ The superior fibres arch beneath the Levator palati and the Eustachian tube. The interval between the upper border of the muscle and the basilar process is deficient in muscle fibres and is closed by a portion of the **pharyngeal aponeurosis** (*fascia pharyngobasilaris*). This interval is known as the **sinus of Morgagni**.

Relations.—By its *superficial surface* the Superior constrictor is in relation with the prevertebral fascia and muscles, the vertebral column, the internal carotid and ascending pharyngeal arteries, the internal jugular vein and pharyngeal venous plexus, the glossopharyngeal, vagus, spinal accessory, hypoglossal, lingual, and sympathetic nerves, the Middle constrictor and Internal pterygoid muscles, the styloid process, the stylohyoid ligament, and the Stylopharyngeus. By its *deep surface*, it is in relation with the Palatopharyngeus, the tonsil, the fibrous coat, and the mucous membrane of the pharynx.

¹ Accessory bundles of origin sometimes arise from the margins of the middle lacerated foramen and descend to blend with the main muscle mass.

The **Stylopharyngeus** (*m. stylopharyngeus*) is a long, slender muscle, cylindrical above, broad and thin below. It arises from the inner side of the base of the styloid process of the temporal bone, passes downward along the side of the pharynx between the Superior and Middle constrictors, and spreads out beneath the mucous membrane, where some of its fibres are lost in the Constrictor muscles; and others, joining with the Palatopharyngeus, are inserted into the posterior border of the thyroid cartilage. The glossopharyngeal nerve runs on the outer side of this muscle, and crosses over it in passing forward to the tongue.

FIG. 307.—The muscles of the pharynx. On the right side most of the Inferior constrictor has been removed, on the left side the Digastric and Stylohyoid have been removed. (Spalteholz.)

Relations.—By its *superficial surface*, with the Styloglossus muscle, the parotid gland, the external carotid artery, and the Middle constrictor; by its *deep surface*, with the internal carotid, the internal jugular vein, the Superior constrictor, Palatopharyngeus, and pharyngeal mucous membrane.

Nerves.—The Constrictors are supplied by branches from the pharyngeal plexus formed by the vagus, glossopharyngeal, and sympathetic nerves. The Inferior constrictor also receives an additional branch from the external laryngeal nerve and one from the recurrent laryngeal. The Stylopharyngeus is supplied by a branch from the glossopharyngeal nerve.

Actions.—When deglutition is about to be performed, the pharynx is drawn upward and dilated in different directions, to receive the bolus propelled into it from the mouth. The Stylo-pharyngei, which are much farther removed from one another at their origin than at their insertion, draw the sides of the pharynx upward and outward, and so increase its transverse diameter; its breadth in the antero-posterior direction is increased by the larynx and tongue being carried forward in their ascent. As soon as the bolus is received in the pharynx, the Elevator muscles relax, the bag descends, and the Constrictors contract upon the bolus, and convey it gradually downward into the oesophagus. Besides its action in deglutition, the pharynx also exerts an important influence in the modulation of the voice, especially in the production of the higher tones.

6. The Palatal Region (Fig. 308).

Levator palati.

Tensor palati.

Azygos uvulae.

Palatoglossus.

Palatopharyngeus.

Salpingopharyngeus.

Dissection (Fig. 308).—Lay open the pharynx from behind by a vertical incision extending from its upper to its lower part, and partially divide the occipital attachment by a transverse incision on each side of the vertical one; the posterior surface of the soft palate is then exposed. Having fixed the uvula so as to make it tense, the mucous membrane and glands should be carefully removed from the posterior surface of the soft palate, and the muscles of this part are at once exposed.

The **Levator palati** (*m. levator veli palatini*) is a long, thick, rounded muscle, placed on the outer side of the posterior nares. It arises from the under surface of the apex of the petrous portion of the temporal bone, and from the inner surface of the cartilaginous portion of the Eustachian tube; after passing into the pharynx, above the upper concave margin of the Superior constrictor, it passes obliquely downward and inward, its fibres spreading out into the soft palate as far as the middle line, where they blend with those of the opposite side.

Relations.—By its *superficial surface*, this muscle is in relation with the Tensor palati, the Superior constrictor, and the Eustachian tube; by its *deep surface*, with the mucous membrane of the pharynx; *posteriorly*, with the posterior fasciculus of the Palatopharyngeus, the Azygos uvulae, and the mucous membrane of the soft palate.

The **Tensor palati** (*m. tensor veli palatini*) is a broad, thin, ribbon-like muscle, placed on the outer side of the Levator palati, and consisting of a vertical and a horizontal portion. The **vertical portion** arises by a flat lamella from the scaphoid fossa at the base of the internal pterygoid plate; from the spine of the sphenoid and from the outer side of the cartilaginous portion of the Eustachian tube; it descends vertically between the internal pterygoid plate and the inner surface of the Internal pterygoid muscle, and terminates in a tendon, which winds around the hamular process, being retained in this situation by some of the fibres of origin of the Internal pterygoid muscle. Between the hamular process and the tendon is a small bursa (*bursa m. tensoris veli palati*). The **tendon** or **horizontal portion** then passes horizontally inward, and is inserted into a broad aponeurosis, the **palatal aponeurosis**, and into the transverse ridge on the horizontal portion of the palate bone.

Relations.—By its *superficial surface*, this muscle is in relation with the Internal pterygoid; by its *deep surface*, with the Levator palati, from which it is separated by the Eustachian tube and Superior constrictor, and with the internal pterygoid plate. In the soft palate its tendon and the palatal aponeurosis are anterior to those of the Levator palati, being covered by the Palatoglossus and the mucous membrane.

Palatal Aponeurosis.—Attached to the posterior border of the hard palate is a thin, firm, fibrous lamella which supports the muscles and gives strength to the

soft palate. It is thicker above than below, where it becomes very thin and difficult to define. Laterally, it is continuous with the pharyngeal aponeurosis.

The **Axygos uvulae** (*m. uvulae*) is not a single muscle, as would be inferred from its name, but a pair of narrow cylindrical fleshy fasciculi placed on either side of the median line of the soft palate. Each muscle *arises* from the posterior nasal spine of the palate bone and from the contiguous tendinous aponeurosis of the soft palate, and descends to be *inserted* into the uvula.

Relations.—*Anteriorly*, with the tendinous expansion of the Levatores palati; *posteriorly*, with the posterior fasciculus of the Palatopharyngeus and the mucous membrane.

The next two muscles are exposed by removing the mucous membrane from the pillars of the fauces throughout nearly their whole extent.

FIG. 308.—Muscles of the soft palate, the pharynx being laid open from behind.

The **Palatoglossus** (*m. glossopalatinus*) is a small fleshy fasciculus, narrower in the middle than at either extremity, forming, with the mucous membrane covering its surface, the anterior pillar of the soft palate. It *arises* from the anterior surface of the soft palate on each side of the uvula, and, passing downward, forward, and outward in front of the tonsil, is *inserted* into the side of the tongue, some of its fibres spreading over the dorsum, and others passing deeply into the substance of the organ to intermingle with the Transverse lingualis. In the soft palate the fibres of this muscle are continuous with those of the muscle of the opposite side.

The **Palatopharyngeus** (*m. pharyngopalatinus*) is a long, fleshy fasciculus, narrower in the middle than at either extremity, forming, with the mucous,

membrane covering its surface, the posterior pillar of the soft palate. It is separated from the Palatoglossus by an angular interval, in which the tonsil is lodged. It *arises* from the soft palate by an expanded fasciculus, which is divided into two parts by the Levator palati and Azygos uvulae. The **posterior fasciculus** lies in contact with the mucous membrane, and also joins with the corresponding muscle in the middle line; the **anterior fasciculus**, the thicker, lies in the soft palate between the Levator and Tensor, and joins in the middle line the corresponding part of the opposite muscle. Passing outward and downward behind the tonsil, the Palatopharyngeus joins the Stylopharyngeus, and is *inserted* with that muscle into the posterior border of the thyroid cartilage, some of its fibres being lost on the side of the pharynx, and others passing across the middle line posteriorly to decussate with the muscle of the opposite side.

Relations.—In the soft palate its *posterior surface* is covered by mucous membrane, from which it is separated by a layer of palatal glands. By its *anterior surface* it is in relation with the Tensor palati. Where it forms the posterior pillar of the fauces it is covered by mucous membrane, excepting on its outer surface. In the *pharynx* it lies between the mucous membrane and the Constrictor muscles.

The **Salpingopharyngeus** (*m. salpingopharyngeus*) *arises* from the inferior part of the Eustachian tube near its orifice; it passes downward and blends with the posterior fasciculus of the Palatopharyngeus.

In a dissection of the soft palate from its posterior or nasal surface to its anterior or oral surface, the muscles would be exposed in the following order—viz., the posterior fasciculus of the Palatopharyngeus, covered over by the mucous membrane reflected from the floor of the nasal fossæ; the Azygos uvulae; the Levator palati; the anterior fasciculus of the Palatopharyngeus; the aponeurosis of the Tensor palati, and the Palatoglossus, covered over by a reflection from the oral mucous membrane.

Nerves.—The Tensor palati is supplied by a branch from the otic ganglion; the remaining muscles of this group are in all probability supplied by the internal branch of the spinal accessory, the fibres of which are distributed along with certain branches of the vagus through the pharyngeal plexus.¹

Actions.—During the *first stage* of deglutition the bolus of food is driven back into the fauces by the pressure of the tongue against the hard palate; the base of the tongue is, at the same time, retracted, and the larynx is raised with the pharynx, and carried forward under it. During the *second stage* the entrance to the larynx is closed, not, as was formerly supposed, by the folding backward of the epiglottis over it, but, as Anderson Stuart has shown, by the drawing forward of the arytenoid cartilages toward the cushion of the epiglottis—a movement produced by the contraction of the External thyroarytenoid, the Arytenoid, and Aryteno-epiglottidean muscles.

The bolus of food after leaving the tongue passes on to the posterior or laryngeal surface of the epiglottis, and glides along this for a certain distance;² then the Palatoglossi muscles, the constrictors of the fauces, contract behind the food; the soft palate is slightly raised by the Levatores palati, and made tense by the Tensores palati; and the Palatopharyngei, by their contraction, pull the pharynx upward over the bolus of food, and at the same time come nearly together, the uvula filling up the slight interval between them. By these means the food is prevented from passing into the upper part of the larynx or the posterior nares; at the same time the latter muscles form an inclined plane, directed obliquely downward and backward, along the under surface of which the bolus descends into the lower part of the pharynx. Each Salpingopharyngeus raises the upper and lateral part of the pharynx—*i. e.*, that part which is above the point where the Stylopharyngeus is attached to the pharynx.

Applied Anatomy.—After operation for cleft palate the Tensor palati and Levator palati retard union by causing undue tension along the line of suture. In order to overcome this it is necessary to divide these muscles, and this is done by making longitudinal incisions on either side, parallel to the cleft and just internal to the hamular process, in such a position as to avoid the posterior palatine artery.

¹ Journal of Anatomy and Physiology, vol. xxiii, p. 523.

² We now know that normal deglutition can be carried out when the epiglottis is so small that it cannot cover the opening into the larynx, or when it has been removed surgically. In such cases the sphincter muscles which surround the laryngeal aperture contract during swallowing and prevent the entrance of foreign bodies into the larynx.

7. The Anterior Vertebral Region (Fig. 309).

Rectus capitis anticus major.
Rectus capitis anticus minor.

Rectus capitis lateralis.
Longus colli.

The **Rectus capitis anticus major** (*m. longus capitis*), broad and thick above and narrow below, appears like a continuation upward of the *Scalenus anticus*. It *arises* by four tendinous slips from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ, and ascends, converging toward its fellow of the opposite side, to be *inserted* into the basilar process of the occipital bone.

Relations.—By its *deep surface*, this muscle is in relation with the pharynx, the inferior cervical sympathetic ganglion and nerve, and the sheath enclosing the internal and common carotid artery, internal jugular vein, and vagus nerve; by its *superficial surface*, with the *Longus colli*, the *Rectus capitis anticus minor*, and the upper cervical vertebræ.

FIG. 309.—The prevertebral muscles (ventral view).

The **Rectus capitis anticus minor** (*m. rectus capitis anterior*) is a short, flat muscle, situated immediately behind the upper part of the preceding. It *arises* from the anterior surface of the lateral mass of the atlas and from the root of its transverse process, and, passing obliquely upward and inward, is *inserted* into the basilar process immediately behind the rectus capitis anticus major.

The **Rectus capitis lateralis** (*m. rectus capitis lateralis*) is a short, flat muscle, which *arises* from the upper surface of the transverse process of the atlas and is

inserted into the under surface of the jugular process of the occipital bone. This muscle lies behind the internal jugular vein, and in front of the upper portion of the vertebral artery.

The **Longus colli** (*m. longus colli*) is a long, flat muscle, situated on the anterior surface of the vertebral column, between the atlas and the third thoracic vertebra. It is broad in the middle, narrow and pointed at each extremity, and consists of three portions—a superior oblique, an inferior oblique, and a vertical portion. The **superior oblique portion** *arises* from the anterior tubercles of the transverse processes of the third, fourth, and fifth cervical vertebrae, and, ascending obliquely inward, is *inserted* by a narrow tendon into the tubercle on the anterior arch of the atlas. The **inferior oblique portion**, the smallest part of the muscle, *arises* from the front of the bodies of the first two or three thoracic vertebrae, and, ascending obliquely outward, is *inserted* into the anterior tubercles of the transverse processes of the fifth and sixth cervical vertebrae. The **vertical portion** lies directly on the front of the vertebral column; it *arises*, below, from the front of the bodies of the upper three thoracic and lower three cervical vertebrae, and is *inserted* above into the front of the bodies of the second, third, and fourth cervical vertebrae.

Relations.—By its *deep surface*, with the prevertebral fascia, the pharynx, œsophagus, sympathetic nerve, the sheath of the great vessels of the neck, the inferior thyroid artery, and the recurrent laryngeal nerve; by its *superficial surface*, with the cervical and thoracic portions of the vertebral column. Its *inner border* is separated from the opposite muscle by a considerable interval below, but they approach each other above.

Nerves.—The Rectus capitis anticus minor and the Rectus lateralis are supplied from the loop between the first and second cervical nerves; the Rectus capitis anticus major, by branches from the second, third, and fourth cervical; the Longus colli, by branches from the second to the seventh cervical nerves.

Actions.—The Rectus anticus major and minor are the direct antagonists of the muscles at the back of the neck, serving to restore the head to its natural position after it has been drawn backward. These muscles also serve to flex the head, and, from their obliquity, rotate it, so as to turn the face to one or the other side. The Longus colli flexes and slightly rotates the cervical portion of the vertebral column.

8. The Lateral Vertebral Region (Figs. 309, 310).

Scalenus anticus.

Scalenus medius.

Scalenus posticus.

The **Scalenus anticus** (*m. scalenus anterior*) is a conical-shaped muscle, situated deeply at the side of the neck, behind the Sternomastoid. It *arises* from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebrae, and, descending almost vertically, is *inserted* by a narrow, flat tendon into the scalene tubercle on the inner border and upper surface of the first rib. The lower part of this muscle separates the subclavian artery and vein, the latter being in front, and the former, with the brachial plexus, behind.

Relations.—By its *superficial surface*, this muscle is in relation with the clavicle, the Subclavius, Sternomastoid, and Omohyoid muscles, the transversalis colli, and the suprascapular arteries, the subclavian vein, and the phrenic nerve; by its *deep surface*, with the Scalenus medius, pleura, subclavian artery, and brachial plexus of nerves. It is separated from the Longus colli, on the inner side, by the vertebral artery. On the anterior tubercles of the transverse processes of the cervical vertebrae, between the attachments of the Scalenus anticus and Longus colli lies the ascending cervical branch of the inferior thyroid artery.

The **Scalenus medius** (*m. scalenus medius*), the largest and longest of the three Scaleni, *arises* from the posterior tubercles of the transverse processes of the lower six cervical vertebrae, and, descending along the side of the vertebral column,

is inserted by a broad attachment into the upper surface of the first rib, behind the groove for the subclavian artery, as far back as the tubercle. It is separated from the *Scalenus anticus* by the subclavian artery below and by the cervical nerves above. The posterior thoracic, or nerve of Bell, is formed in the substance of the *Scalenus medius* and emerges from it. The nerve to the Rhomboids also pierces it.

Relations.—By its *superficial surface*, with the *Sternomastoid*; it is crossed by the clavicle, the *Omohyoid* muscle, subclavian artery, and cervical nerves. To its *outer side* is the *Levator anguli scapulae* and the *Scalenus posticus* muscle.

The ***Scalenus posticus*** (*m. scalenus posterior*), the smallest of the three *Scaleni*, arises, by two or three separate tendons, from the posterior tubercles of the transverse processes of the lower two or three cervical vertebrae, and, diminishing as it descends, is inserted by a thin tendon into the outer surface of the second rib, behind the attachment of the *Serratus magnus*. This is the most deeply placed of the three *Scaleni*, and is occasionally blended with the *Scalenus medius*.

Nerves.—The *Scalenus anticus* receives branches from the fourth to the seventh cervical; the *Scalenus medius* from the third to the eighth cervical; and the *Scalenus posticus*, from the fourth to the eighth cervical nerves.

Actions.—The *Scaleni* muscles, when they take their fixed point from above, elevate the first and second ribs, and are, therefore, inspiratory muscles. When they take their fixed point from below, they bend the vertebral column to one or the other side. If the muscles of both sides act, lateral movement is prevented, but the vertebral column is slightly flexed. The *Rectus lateralis*, acting on one side, bends the head laterally.

Surface Form.—The muscles in the neck, with the exception of the *Platysma*, are invested by the deep cervical fascia, which softens down their form, and is of considerable importance in connection with deep cervical abscesses and tumors, modifying the direction of the growth of tumors and of the enlargement of abscesses, and causing them to extend laterally instead

of toward the surface. The *Platysma* does not influence surface form except when in action, when it produces wrinkling of the skin of the neck, which is thrown into oblique ridges parallel with the fasciculi of the muscle. Sometimes this contraction takes place suddenly and repeatedly as a sort of spasmodic twitching, the result of a nervous habit. The *Sternomastoid* is the most important muscle of the neck as regards its surface form. If the muscle is put into action by drawing the chin downward and to the opposite shoulder, its surface form will be plainly outlined. The sternal origin will stand out as a sharply defined ridge, while the clavicular origin will present a flatter and not so prominent outline. The fleshy middle portion will appear as an oblique roll or elevation, with a thick, rounded anterior border gradually becoming less marked above. On the opposite side—i. e., on the side to which the head is turned—the outline is lost, its place being occupied by an oblique groove in the integument. When the muscle is at rest its anterior border is still visible, forming an oblique rounded ridge, terminating below in a sharp outline of the sternal head. The posterior border of the muscle does not show above the clavicular head. The anterior border is defined by drawing a line from the tip of the mastoid process to the sternoclavicular joint. It is an important surface-marking in the operation

FIG. 310.—Scaleni muscles. (Poirier and Charpy.)

of ligation of the common carotid artery and in some other operations. Between the *sternal* and clavicular heads is a slight depression, most marked when the muscle is in action. This is bounded below by the prominent sternal extremity of the clavicle. Between the sternal origins of the two muscles is a V-shaped space, the *suprasternal notch*, more pronounced below, and becoming toned down above, where the Sternohyoid and Sternothyroid muscles, lying upon the trachea, become more prominent. Above the hyoid bone, in the middle line, the anterior belly of the *Digastric* to a certain extent influences surface form. It corresponds to a line drawn from the symphysis of the mandible to the side of the body of the hyoid bone, and renders convex this part of the hyomental region. In the posterior triangle of the neck, the posterior belly of the *Omothyoid*, when in action, forms a conspicuous object, especially in thin necks, presenting a cord-like form running across this region, almost parallel with, and a little above, the clavicle.

MUSCLES AND FASCIÆ OF THE TRUNK.

The muscles of the Trunk may be arranged in four groups, corresponding with the region in which they are situated.

- | | |
|-----------------|-------------------|
| I. The Back. | III. The Abdomen. |
| II. The Thorax. | IV. The Perineum. |

I. MUSCLES OF THE BACK.

The muscles of the back are very numerous, and may be subdivided into five layers:

FIRST LAYER.

Trapezius.
Latissimus dorsi.

Longissimus dorsi.
Spinalis dorsi.

SECOND LAYER.

Levator anguli scapulae.
Rhomboides minor.
Rhomboides major.

Cervical Region.
Cervicalis ascendens.
Transversalis cervicis.
Trachelomastoid.
Complexus.
Biventer cervicis.
Spinalis colli.

THIRD LAYER.

Serratus posticus superior.
Serratus posticus inferior.
Splenius capitis.
Splenius colli.

FOURTH LAYER.

Sacral and Lumbar Regions.
Erector spinae

Dorsal Region.

Iliocostalis.
Musculus accessorius ad iliocostalem

FIFTH LAYER.

Semispinalis dorsi.
Semispinalis colli.
Multifidus spinae.
Rotatores spinae.
Supraspinales.
Interspinales.
Extensor coccygis.
Intertransversalis.
Rectus capitis posticus major.
Rectus capitis posticus minor.
Obliquus capitis inferior.
Obliquus capitis superior.

The First Layer (Fig. 312).

Trapezius.

Latissimus dorsi.

Dissection (Fig. 311).—Place the body in a prone position, with the arms extended over the sides of the table, and the thorax and abdomen supported by several blocks, so as to render the muscles tense. Then make an incision along the middle line of the back from the occipital protuberance to the coccyx. Make a transverse incision from the upper end of this to the mastoid process, and a third incision from its lower end, along the crest of the ilium to about its middle. This large intervening space should, for convenience of dissection, be subdivided by a fourth incision, extending obliquely from the spinous process of the last thoracic vertebra, upward and outward, to the acromion process. This incision corresponds with the lower border of the Trapezius muscle. The flaps of integument are then to be removed in the direction shown in the figure.

The **superficial fascia** is exposed upon removing the skin from the back. It forms a layer of considerable thickness and strength, in which a quantity of granular pinkish fat is contained. It is continuous with the superficial fascia in other parts of the body.

The **deep fascia** is a dense fibrous layer attached to the occipital bone, the spines of the vertebræ, the crest of the ilium, and the spine of the scapula. It covers over the superficial muscles, forming sheaths for them, and in the neck forms the posterior part of the deep cervical fascia; in the thorax it is continuous with the deep fascia of the axilla and thorax, and in the abdomen with that covering the abdominal muscles. In the back of the thoracic region the deep fascia is called the **vertebral aponeurosis**. It covers the Erector spinae muscles, and is the dorsal layer of the lumbar fascia.

The **Trapezius** (*m. trapezius*) is a broad, flat, triangular muscle, placed immediately beneath the skin and fascia, and covering the upper and back part of the neck and shoulders. It *arises* from the external occipital protuberance and the inner third of the superior curved line of the occipital bone; from the ligamentum nuchæ, the spinous process of the seventh cervical, and the spinous processes of all the thoracic vertebræ; and from the corresponding portion of the supraspinous ligament. From this origin the superior fibres proceed downward and outward, the inferior ones upward and outward, the middle fibres horizontally, and are *inserted*, the superior ones into the outer third of the posterior border of the clavicle and into the adjacent part of its upper surface. The middle fibres pass into the inner margin of the acromion process, and into the superior lip of the posterior border or crest of the spine of the scapula; the inferior fibres converge near the scapula, and terminate in a triangular aponeurosis, which glides over a smooth surface at the inner extremity of the spine, to be *inserted* into a tubercle at the outer part of this smooth surface. The Trapezius is fleshy in the greater part of its extent, but tendinous at its origin and insertion. At its occipital origin

FIG. 311.—Dissection of the muscles of the back.

FIG. 312.—Muscles of the back. On the left side is exposed the first layer; on the right side, the second layer and part of the third.

it is connected to the bone by a thin fibrous lamina, firmly adherent to the skin, and wanting the lustrous, shining appearance of aponeuroses. At its origin from the spines of the vertebræ it is connected to the bones by means of a broad semi-elliptical aponeurosis, which occupies the space between the sixth cervical and the third thoracic vertebræ, and forms, with the aponeurosis of the opposite muscle, a tendinous ellipse. The rest of the muscle arises by numerous short tendinous fibres. If the Trapezius is dissected on both sides, the two muscles resemble a trapezium or diamond-shaped quadrangle; two angles corresponding to the shoulders; a third to the occipital protuberance; and the fourth to the spinous process of the last thoracic vertebra. The clavicular insertion of this muscle varies as to the extent of its attachment; it sometimes advances as far as the middle of the clavicle, and may even become blended with the posterior edge of the Sternomastoid or may overlap it. This should be borne in mind in the operation for tying the third part of the subclavian artery.

Relations.—By its *superficial surface*, the Trapezius is in relation with the integument; by its *deep surface*, in the neck, with the Complexus, Splenius, Levator anguli scapulae, and Rhomboideus minor; in the back, with the Rhomboideus major, Supraspinatus, Infraspinatus, and vertebral aponeurosis (which separates it from the prolongations of the Erector spinae), and the Latissimus dorsi. The spinal accessory nerve and the superficial cervical artery and branches from the third and fourth cervical nerves pass beneath the anterior border of this muscle. The anterior margin of its cervical portion forms the posterior boundary of the posterior triangle of the neck, the other boundaries being the Sternomastoid in front and the clavicle below.

The **Ligamentum nuchæ** (Fig. 312) is a fibrous membrane, which, in the neck, represents the supraspinous and interspinous ligaments of the lower vertebræ. It extends from the external occipital protuberance to the spinous process of the seventh cervical vertebra. From its anterior border a fibrous lamina (*fascia nuchæ*) is given off, which is attached to the external occipital crest, the posterior tubercle of the atlas, and the spinous process of each of the cervical vertebræ, so as to form a septum between the muscles on each side of the neck. In man it is merely the rudiment of an important elastic ligament, which, in some of the lower animals, serves to sustain the weight of the head.

The **Latissimus dorsi** (*m. latissimus dorsi*) is a broad, flat muscle, which covers the lumbar and the lower half of the thoracic regions, and is gradually contracted into a narrow fasciculus at its insertion into the humerus. It *arises* by tendinous fibres from the spinous processes of the six inferior thoracic vertebræ and from the dorsal layer of the lumbar fascia (see page 410), by which it is attached to the spines of the lumbar and sacral vertebræ and to the supraspinous ligament. It also *arises* from the external lip of the crest of the ilium, behind the insertion of the External oblique muscle, and by fleshy digitations from the three or four lower ribs, which are interposed between similar processes of the External oblique (Fig. 319, page 426). From this extensive origin the fibres pass in different directions, the upper ones horizontally, the middle obliquely upward, and the lower vertically upward, so as to converge and form a thick fasciculus, which crosses the inferior angle of the scapula, and which usually receives a few fibres of origin from it. The muscle curves around the lower border of the Teres major, and is twisted upon itself so that the superior fibres become at first posterior and then inferior, and the vertical fibres at first anterior and then superior. It terminates in a short quadrilateral tendon, about three inches in length, which, passing in front of the tendon of the Teres major, is *inserted* into the bottom of the bicipital groove of the humerus, its insertion extending higher on the humerus than that of the tendon of the Pectoralis major. The lower border of the tendon of this muscle is united with that of the Teres major, the surfaces of the two being separated near their insertions by a bursa; another bursa is sometimes interposed

Nerves.—The Rhomboid muscles are supplied by branches from the anterior division of the fifth cervical nerve; the Levator anguli scapulae, by the anterior divisions of the third and fourth cervical nerves, and frequently by a branch from the nerve to the Rhomboids.

Actions.—The movements effected by the preceding muscles are numerous, as may be conceived from their extensive attachment. The whole of the Trapezius when in action retracts the scapula and braces back the shoulder; if the head is fixed, the upper part of the Trapezius will elevate the point of the shoulder, as in supporting weights; when the lower fibres are brought into action, they assist in depressing the bone. The middle and lower fibres of the muscle rotate the scapula, causing elevation of the acromion process. If the shoulders are fixed, both Trapezii, acting together, will draw the head directly backward; or if only one acts the head is drawn to the corresponding side. The Latissimus dorsi, when it acts upon the humerus, depresses it, draws it backward, adducts, and at the same time rotates it inward. It is the muscle which is principally employed in giving a downward blow, as in felling a tree or in sabre practice. If the arm is fixed, the muscle may act in various ways upon the trunk; thus, it may raise the lower ribs and assist in forcible inspiration; or, if both arms are fixed, the two muscles may assist the Abdominal and great Pectoral muscles in suspending and drawing the whole trunk forward, as in climbing or walking on crutches. The Levator anguli scapulae raises the superior angle of the scapula, and by so doing depresses the point of the shoulder. It assists the Trapezius in bearing weights and in shrugging the shoulders. If the shoulder be fixed, the Levator anguli scapulae inclines the neck to the corresponding side and rotates it in the same direction. The Rhomboid muscles carry the inferior angle backward and upward, thus producing a slight rotation of the scapula upon the side of the thorax, the Rhomboideus major acting especially on the lower angle of the scapula through the tendinous arch by which it is inserted. The Rhomboid muscles, acting together with the middle and inferior fibres of the Trapezius, will draw the scapula directly backward toward the vertebral column.

The Third Layer.

Serratus posticus superior.

Serratus posticus inferior.

Splenius { Splenius capitis.
Splenius colli.

Dissection.—To bring into view the third layer of muscles, remove the whole of the second, together with the Latissimus dorsi, by cutting through the Levator anguli scapulae and Rhomboid muscles near their origin, and reflecting them downward, and by dividing the Latissimus dorsi in the middle by a vertical incision carried from its upper to its lower part, and reflecting the two halves of the muscle.

The **Serratus posticus superior** (*m. serratus posterior superior*) is a thin, flat quadrilateral muscle situated at the upper and back part of the thorax. It arises by a thin and broad aponeurosis from the ligamentum nuchae, and from the spinous processes of the last cervical and two or three upper thoracic vertebræ and from the supraspinous ligament. Inclining downward and outward, it becomes muscular, and is inserted, by four fleshy digitations, into the upper borders of the second, third, fourth, and fifth ribs, a little beyond their angles.

The **Serratus posticus inferior** (*m. serratus posterior inferior*) (Fig. 312) is situated at the junction of the thoracic and lumbar regions; it is of an irregularly quadrilateral form, broader than the preceding, and separated from it by a considerable interval. It arises by a thin aponeurosis from the spinous processes of the last two thoracic and two or three upper lumbar vertebræ, and from the supraspinous ligaments. Passing obliquely upward and outward, it becomes fleshy, and divides into four flat digitations, which are inserted into the lower borders of the four lower ribs, a little beyond their angles. The thin aponeurosis of origin is intimately blended with the lumbar fascia.

The **vertebral aponeurosis** is a thin, fibrous lamina, extending along the whole length of the back part of the thoracic region, serving to bind down the long Extensor muscles of the back which support the vertebral column and head, and separate them from those muscles which connect the vertebral column to the upper

extremity. It consists of longitudinal and transverse fibres blended together, forming a thin lamella, which is attached, in the median line, to the spinous processes of the thoracic vertebræ; externally, to the angles of the ribs; and is continuous with the intercostal fascia below. It is continuous below with the aponeurosis of the Serratus posticus inferior and a portion of the lumbar fascia, which gives origin to the Latissimus dorsi; above, it passes beneath the Serratus posticus superior and the Splenius, and blends with the deep fascia of the neck.

The **lumbar fascia or aponeurosis** (Figs. 312 and 327), which may be regarded as the posterior aponeurosis of the Transversalis abdominis muscle, consists of three laminae, which are attached as follows: The **dorsal layer**, to the spines of the lumbar and sacral vertebræ and their supraspinous ligaments; the **middle layer**, to the tips of the transverse processes of the lumbar vertebræ and their intertransverse ligaments; the **ventral layer**, to the roots of the lumbar transverse processes. The dorsal layer is continued above as the vertebral aponeurosis, while inferiorly it is fixed to the outer lip of the iliac crest. With this layer are blended the aponeurotic origin of the Serratus posticus inferior and part of that of the Latissimus dorsi. The middle layer is attached above to the last rib, and below to the iliac crest; the ventral layer is fixed below to the iliolumbar ligament and iliac crest; while above it is thickened to form the external arcuate ligament of the Diaphragm, and stretches from the tip of the last rib to the transverse process of the first or second lumbar vertebra. These three layers, together with the vertebral column, enclose two spaces, the posterior of which is occupied by the Erector spinae muscle, and the anterior by the Quadratus lumborum.

Now detach the Serratus posticus superior from its origin, and turn it outward, when the Splenius muscle will be brought into view.

The **Splenius muscle mass** (Fig. 312) is situated at the back of the neck and upper part of the thoracic region. At its origin it is a single muscle, which soon after its origin becomes broad, and divides into two portions, which have separate insertions. It *arises*, by tendinous fibres, from the lower half of the ligamentum nuchae, from the spinous processes of the last cervical and of the six upper thoracic vertebræ, and from the supraspinous ligament. From this origin the fleshy fibres proceed obliquely upward and outward, forming a broad, flat muscle sheet, which divides as it ascends into two portions, the **Splenius capitis** and **Splenius colli**.

The **Splenius capitis** (*m. splenius capitis*) is *inserted* into the mastoid process of the temporal bone, and into the rough surface on the occipital bone, just beneath the superior curved line.

The **Splenius colli** (*m. splenius cervicis*) is *inserted*, by tendinous fasciculi, into the posterior tubercles of the transverse processes of the two or three upper cervical vertebræ.

The Splenius muscles are separated from their fellows of the opposite side by a triangular interval, in which is seen the Complexus.

Nerves.—The Splenius capitis and colli muscles are supplied from the external branches of the posterior primary divisions of the middle and lower cervical nerves; the Serratus posticus superior is supplied by the external branches of the upper three or four intercostal nerves; the Serratus posticus inferior by branches of the ninth, tenth, and eleventh intercostal nerves.

Actions.—The Serrati are respiratory muscles. The Serratus posticus superior elevates the ribs; it is therefore an inspiratory muscle; while the Serratus inferior draws the lower ribs downward and backward, and thus elongates the thorax. It also fixes the lower ribs, thus aiding the downward action of the Diaphragm and resisting the tendency which it has to draw the lower ribs upward and forward. It must therefore be regarded as a muscle of inspiration. This muscle is also probably a tensor of the vertebral aponeurosis. The Splenii muscles of the two sides, acting together, draw the head directly backward, assisting the Trapezius and Complexus; acting separately, they draw the head to one or the other side, and slightly rotate it, turning the face to the same side. They also assist in supporting the head in the erect position.

The Fourth Layer (Fig. 313).**I. Erector spinae.****a. Outer Column.**

Iliocostalis.
Musculus accessorius.
Cervicalis ascendens.

b. Middle Column

Longissimus dorsi.
Transversalis cervicis.
Trachelomastoid.

c. Inner Column.

Spinalis dorsi.

Spinalis colli.

II. Complexus.

Dissection.—To expose the muscles of the fourth layer, remove entirely the *Serrati* and the vertebral and lumbar fasciae. Then detach the *Splenius* by separating its attachment to the spinous processes and reflecting it outward.

The **Erector spinae** (*m. sacrospinalis*) and its prolongations in the thoracic and cervical regions fill up the vertebral groove on each side of the vertebral column. It is covered in the lumbar region by the lumbar fascia; in the thoracic region, by the *Serrati* muscles and the vertebral aponeurosis; and in the cervical region, by a layer of cervical fascia continued beneath the *Trapezius* and the *Splenius*. This large muscular and tendinous mass varies in size and structure at different parts of the vertebral column. In the sacral region the *Erector spinae* is narrow and pointed, and its origin is chiefly tendinous in structure. In the lumbar region the muscle becomes enlarged, and forms a large, fleshy mass. In the thoracic region it subdivides into two parts, which gradually diminish in size as they ascend to be inserted into the vertebræ and ribs.

The *Erector spinae* arises from the anterior surface of a very broad and thick tendon, the *erector spinae aponeurosis*, which is attached, *internally*, to the spines of the sacrum, to the spinous processes of the lumbar and the eleventh and twelfth thoracic vertebræ, and to the supraspinous ligament; *externally*, to the back part of the inner lip of the crest of the ilium, and to the series of eminences on the posterior part of the sacrum, which represents the transverse processes, where it blends with the great sacrosciatic and posterior sacroiliac ligaments. Some of its fibres are continuous with the fibres of origin of the *Gluteus maximus*. The muscle fibres form a single large fleshy mass, bounded in front by the transverse processes of the lumbar vertebræ and by the middle lamella of the lumbar fascia. Opposite the last rib it divides into three parts: (1) The ***Iliocostalis***; (2) the ***Longissimus dorsi***; and (3) the ***Spinalis dorsi***.

1. The ***Iliocostalis*** (*m. iliocostalis lumborum*), the external portion of the *Erector spinae*, is *inserted*, generally, by six or seven flattened tendons into the inferior borders of the angles of the six or seven lower ribs. The number of the tendons of this muscle is, however, quite variable, and therefore the number of ribs into which it is inserted varies. Internally this muscle is reinforced by a series of muscle slips which arise from the angles of the ribs; by means of these the *Iliocostalis* is continued upward to the upper ribs and to the cervical portion of the vertebral column. These accessory portions form two additional muscles, the ***Musculus accessorius*** and the ***Cervicalis ascendens***.

The ***Musculus accessorius*** (*m. iliocostalis dorsi*) arises, by separate flattened tendons, from the upper borders of the angles of the six lower ribs; these become muscular, and are finally *inserted*, by separate tendons, into the upper borders of the angles of the six upper ribs and into the back of the transverse processes of the seventh cervical vertebra.

FIG. 313.—Muscles of the back. Deep layers.

The **Cervicalis ascendens** (*m. iliocostalis cervicis*) is the continuation of the Accessorius upward into the neck; it is situated on the inner side of the tendons of the Accessorius, arising from the angles of the four or five upper ribs, and is inserted by a series of slender tendons into the posterior tubercles of the transverse processes of the fourth, fifth, and sixth cervical vertebræ.

2. The **Longissimus dorsi** is the middle and largest portion of the Erector spinae. In the lumbar region, where it is as yet blended with the Iliocostalis, some of the fibres are attached to the whole length of the posterior surface of the transverse processes and the accessory processes of the lumbar vertebræ, and to the middle layer of the lumbar fascia. In the thoracic region the Longissimus dorsi is inserted, by long, thin tendons, into the tips of the transverse processes of all the thoracic vertebræ, and into from seven to eleven of the lower ribs between their tubercles and angles. This muscle is continued upward to the cranium and cervical portion of the vertebral column by means of two additional muscles, the **Transversalis cervicis** and **Trachelomastoid**.

The **Transversalis cervicis** (*m. longissimus cervicis*), placed on the inner side of the Longissimus dorsi, arises by long, thin tendons from the summits of the transverse processes of the six upper thoracic vertebræ, and is inserted by similar tendons into the posterior tubercles of the transverse processes of the cervical vertebræ, from the second to the sixth inclusive.

The **Trachelomastoid** (*m. longissimus capitis*) lies on the inner side of the preceding, between it and the Complexus muscle. It arises, by tendons, from the transverse processes of the five or six upper thoracic vertebræ, and the articular processes of the three or four lower cervical vertebræ. The fibres form a small muscle, which ascends to be inserted into the posterior margin of the mastoid process, beneath the Splenius and Sternomastoid muscles. This small muscle is almost always crossed by a tendinous intersection near its insertion into the mastoid process.¹

3. The **Spinalis dorsi** is situated at the inner side of the Longissimus dorsi, with which it is intimately blended. It arises, by three or four tendons, from the spinous processes of the first two lumbar and the last two thoracic vertebræ; these, uniting, form a small muscle, which is inserted, by separate tendons, into the spinous processes of the thoracic vertebræ, the number varying from four to eight. It is intimately united with the Semispinalis dorsi, which lies beneath it.

The **Spinalis colli** (*m. spinalis cervicis*) is a small muscle, connecting the spinous processes of the cervical vertebræ, and analogous to the Spinalis dorsi in the thoracic region. It varies considerably in its size and in the extent of its attachment to the vertebræ, not only in different bodies, but on the two sides of the same body. It usually arises by fleshy or tendinous slips, varying from two to four in number, from the spinous processes of the fifth, sixth, and seventh cervical vertebræ, and occasionally from the first and second thoracic, and is inserted into the spinous process of the axis, and occasionally into the spinous processes of the two vertebræ below it. This muscle was found absent in five cases out of twenty-four.

The **Complexus** (*m. semispinalis capitis*) is a broad thick muscle, situated at the upper and back part of the neck, beneath the Splenius, and internal to the Transversalis cervicis and Trachelomastoid. It arises, by a series of tendons, from the tips of the transverse processes of the upper six or seven thoracic and the last cervical vertebræ, and from the articular processes of the three cervical vertebræ above this. The tendons, uniting, form a broad muscle, which passes obliquely upward and inward, and is inserted into the innermost depression between the two curved lines of the occipital bone. At about its middle it is traversed

¹ These two muscles (Transversalis cervicis and Trachelomastoid) are sometimes described as one having a common origin, but dividing above at their insertion. The Trachelomastoid is then termed the *Transversalis capitis*.

by a transverse tendinous intersection. The inner portion of this muscle is usually separate and is called the **biventer cervicis**, from the intervention of a tendon between its two fleshy bellies.

The Fifth Layer (Fig. 313).

Semispinalis dorsi.	Extensor coccygis.
Semispinalis colli.	Intertransversales.
Multifidus spinæ.	Rectus capitis posticus major.
Rotatores spinæ.	Rectus capitis posticus minor.
Supraspinales.	Obliquus inferior.
Interspinales.	Obliquus superior.

Dissection.—Remove the muscles of the preceding layer by dividing and turning aside the Complexus; then detach the Spinalis and Longissimus dorsi from their attachments, divide the Erector spinæ at its connection below to the sacral lumbar vertebræ and turn it outward. The muscles filling up the interval between the spinous and transverse processes are then exposed.

The **Semispinalis dorsi** (*m. semispinalis dorsi*) consists of thin, narrow, fleshy fasciculi interposed between tendons of considerable length. It *arises* by a series of small tendons from the transverse processes of the lower thoracic vertebræ, from the tenth or eleventh to the fifth or sixth; and is *inserted*, by five or six tendons, into the spinous processes of the upper four thoracic and lower two cervical vertebræ.

The **Semispinalis colli** (*m. semispinalis cervicis*), thicker than the preceding, *arises* by a series of tendinous and fleshy fibres from the transverse processes of the upper five or six thoracic vertebræ, and is *inserted* into the spinous processes of four cervical vertebræ, from the axis to the fifth cervical. The fasciculus connected with the axis is the largest, and is chiefly muscular in structure.

Superficial to this muscle and the preceding are the profunda cervicis artery, the princeps cervicis artery, and the internal branches of the posterior divisions of the first, second, and third cervical nerves; their *deep surfaces* lie upon the Multifidus spinæ.

The **Multifidus spinæ** (*m. multifidus*) consists of a number of fleshy and tendinous fasciculi which fill up the groove on either side of the spinous processes of the vertebræ, from the sacrum to the axis. In the sacral region these fasciculi *arise* from the back of the sacrum, as low as the fourth sacral foramen, and from the aponeurosis of origin of the Erector spinæ; from the inner surface of the posterior superior spine of the ilium and posterior sacro-iliac ligaments; in the lumbar regions from the mammillary processes; in the thoracic region, from the transverse processes; and in the cervical region, from the articular processes of the three or four lower vertebræ. Each fasciculus, passing obliquely upward and inward, is *inserted* into the whole length of the spinous process of one of the vertebræ above. These fasciculi vary in length; the most superficial, the longest, pass from one vertebra to the third or fourth above; those next in order pass from one vertebra to the second or third above; while the deepest connect two contiguous vertebræ.

Its *superficial surface* is covered by the Semispinalis dorsi, and the Semispinalis colli, and its *deep surface*, lies upon the laminæ and spinous processes of the vertebræ.

The **Rotatores spinæ** (*mm. rotatores*) are found only in the thoracic region of the spine, beneath the Multifidus spinæ; they are eleven in number on each side. Each muscle is small and somewhat quadrilateral in form; and *arises* from the

upper and back part of the transverse process, and is *inserted* into the lower border and outer surface of the lamina of the vertebra above, the fibres extending as far inward as the root of the spinous process. The first is found between the first and second thoracic; the last, between the eleventh and twelfth. Sometimes the number of these muscles is diminished by the absence of one or more from the upper or lower end.

The **Supraspinales** (*mm. supraspinales*) consist of a series of fleshy bands which lie on the spinous processes in the cervical region of the vertebral column.

The **Interspinales** (*mm. interspinales*) are short muscular fasciculi, placed in pairs between the spinous processes of the contiguous vertebræ, one on each side of the interspinous ligament. In the *cervical region* they are most distinct, and consist of *six* pairs, the first being situated between the axis and the third vertebra, and the last between the last cervical and the first thoracic vertebra. They are small narrow bundles, attached, above and below, to the apices of the spinous processes. In the *thoracic region* they are found between the first and second vertebræ, and occasionally between the second and third; and below, between the eleventh and twelfth. In the *lumbar region* there are *four* pairs of these muscles in the intervals between the five lumbar vertebræ. There is also occasionally one in the interspinous space between the last thoracic and first lumbar, and between the fifth lumbar and the sacrum.

The **Extensor coccygis** is a slender muscular fasciculus, occasionally present, which extends over the lower part of the posterior surface of the sacrum and coccyx. It *arises* by tendinous fibres from the last bone of the sacrum or first piece of the coccyx, and passes downward to be *inserted* into the lower part of the coccyx. It is a rudiment of the Extensor muscle of the caudal vertebræ of the lower animals. •

The **Intertransversales** (*mm. intertransversarii*) are small muscles placed between the transverse processes of the vertebræ. In the *cervical region* they are most developed, consisting of rounded muscular and tendinous fasciculi, which are placed in pairs, passing between the anterior and the posterior tubercles of the transverse processes of two contiguous vertebræ, separated from one another by the anterior division of the cervical nerve, which lies in the groove between them. In this region there are *seven* pairs of these muscles, the first pair being between the atlas and axis, and the last pair between the seventh cervical and first thoracic vertebræ. In the *thoracic region* they are least developed, consisting chiefly of rounded tendinous cords in the intertransverse spaces of the upper thoracic vertebræ; but between the transverse processes of the lower three thoracic vertebræ, and between the transverse processes of the last thoracic and the first lumbar, they are muscular in structure. In the *lumbar region* they are arranged in pairs, on either side of the vertebral column, one set occupying the entire interspace between the transverse processes of the lumbar vertebræ, the **intertransversales laterales**; the other set, **intertransversales mediales**, passing from the accessory process of one vertebra to the mammillary process of the next below.

The **Rectus capitis posticus major** (*m. rectus capitis posterior major*) *arises* by a pointed tendinous origin from the spinous process of the axis, and, becoming broader as it ascends, is *inserted* into the inferior curved line of the occipital bone and the surface of bone immediately below it. As the muscles of the two sides pass upward and outward, they leave between them a triangular space, in which are seen the Recti capitis postici minores muscles. The *superficial surface* is crossed by the Complexus; its *deep surface* lies on the posterior occipito-atlantal ligament.

The **Rectus capitis posticus minor** (*m. rectus capitis posterior minor*), the smallest of the four muscles in this region, is of a triangular shape; it *arises* by a narrow pointed tendon from the tubercle on the posterior arch of the atlas, and, becoming broader as it ascends, is *inserted* into the rough surface beneath the inferior.

curved line, nearly as far as the foramen magnum, and nearer to the middle line than the preceding.

The **Obliquus inferior** (*m. obliquus capitis inferior*), the larger of the two Oblique muscles, *arises* from the apex of the spinous process of the axis, and passes outward and slightly upward, to be *inserted* into the lower and back part of the transverse process of the atlas.

The **Obliquus superior** (*m. obliquus capitis superior*), narrow below, wide and expanded above, *arises* by tendinous fibres from the upper surface of the transverse process of the atlas; it joins with the insertion of the preceding, and, passing obliquely upward and inward, is *inserted* into the occipital bone, between the two curved lines, external to the Complexus.

The **Suboccipital triangle** is the triangular interval between the two oblique muscles and the Rectus capitis posticus major. This triangle is bounded, *above* and *internally*, by the Rectus capitis posticus major; *above* and *externally*, by the Obliquus superior; *below* and *externally*, by the Obliquus inferior. It is covered in by a layer of dense fibrofatty tissue, situated beneath the Complexus muscle. The *floor* is formed by the posterior occipito-atlantal ligament and the posterior arch of the atlas. It contains the vertebral artery, as it runs in a deep groove on the upper surface of the posterior arch of the atlas, and the posterior division of the suboccipital nerve.

Nerves.—The fourth and fifth layers of the muscles of the back are supplied by the posterior primary divisions of the spinal nerves.

Actions.—When both the Spinales dorsi contract, they extend the thoracic region of the vertebral column; when only one muscle contracts, it helps to bend the thoracic portion of the vertebral column to one side. The Erector spinae, comprising the Iliocostalis and the Longissimus dorsi with their accessory muscles, serves, as its name implies, to maintain the vertebral column in the erect posture; it also serves to bend the trunk backward when it is required to counterbalance the influence of any weight at the front of the body, as, for instance, when a heavy weight is suspended from the neck, or when there is any great abdominal distention, as in pregnancy or dropsy; the peculiar gait under such circumstances depends upon the vertebral column being drawn backward by the counterbalancing action of the Erector spinae muscles. The muscles which form the continuation of the Erector spinae upward steady the head and neck, and fix them in the upright position. If the Iliocostalis and Longissimus dorsi of one side act, they serve to draw down the thorax and vertebral column to the corresponding side. The Cervicales ascendens, taking their fixed points from the cervical vertebrae, elevate those ribs to which they are attached; taking their fixed points from the ribs, both muscles help to extend the neck; while one muscle bends the neck to its own side. The Transversales cervicis, when both muscles act, taking their fixed point from below, bend the neck backward. The Trachelomastoid, when both muscles act, taking their fixed point from below, bend the head backward; while if only one muscle acts, the face is turned to the side on which the muscle is acting, and then the head is bent to the shoulder. The two Recti muscles draw the head backward. The Rectus capitis posticus major, owing to its obliquity, rotates the cranium, with the atlas, around the odontoid process, turning the face to the same side. The Multifidus spinae acts successively upon the different parts of the vertebral column; thus, the sacrum furnishes a fixed point from which the fasciculi of this muscle act upon the lumbar region; these then become the fixed points for the fasciculi moving the thoracic region, and so on throughout the entire length of the vertebral column; it is by the successive contraction and relaxation of the separate fasciculi of this and other muscles that the spine preserves the erect posture without the fatigue that would necessarily have been produced had this position been maintained by the action of a single muscle. The Multifidus spinae, besides preserving the erect position of the vertebral column, serves to rotate it, so that the front of the trunk is turned to the side opposite to that from which the muscle acts, this muscle being assisted in its action by the Obliquus externus abdominis. The Complexi draw the head directly backward; if one muscle acts, it draws the head to one side, and rotates it so that the face is turned to the opposite side. The Superior oblique draws the head backward, and, from the obliquity in the direction of its fibres, will slightly rotate the cranium, turning the face to the opposite side. The Inferior oblique rotates the atlas, and with it the cranium, around the odontoid process, turning the face to the same side. The Semispinales, when the muscles of the two sides act together, help to extend the vertebral column; when the muscles of one side only act, they rotate the thoracic and cervical parts of the vertebral column, turning the body to the opposite side. The Supraspinales and Interspinales by approximating the spinous processes help to extend the vertebral column. The Intertransversales approximate the transverse processes, and help to bend the vertebral column to one side. The Rotatores spinae assist the Multifidus spinae to

rotate the vertebral column, so that the front of the trunk is turned to the side opposite to that from which the muscle acts.

Surface Forms.—The surface forms produced by the muscles of the back are numerous and difficult to analyze unless they are considered in systematic order. The most superficial layer, consisting of large strata of muscle tissue, influences to a certain extent the surface form, and at the same time reveals the forms of the layers beneath. The *Trapezius* at the upper part of the back, and in the neck, covers over and softens down the outline of the underlying muscles. Its anterior border forms the posterior boundary of the posterior triangle of the neck. It forms a slight undulating ridge which passes downward and forward from the occiput to the junction of the middle and outer third of the clavicle. The tendinous ellipse formed by a part of the origin of the two muscles at the back of the neck is always to be seen as an oval depression, more marked when the muscle is in action. A slight dimple on the skin opposite the interval between the spinous processes of the third and fourth thoracic vertebræ marks the triangular aponeurosis by which the inferior fibres are inserted into the root of the spine of the scapula. From this point the inferior border of the muscle may be traced as an undulating ridge to the spinous process of the twelfth thoracic vertebra. In like manner the *Latissimus dorsi* softens down and modulates the underlying structures at the lower part of the back and lower part of the side of the thorax. In this way it modulates the outline of the *Erector spinae*; of the *Serratus posticus inferior*, which is sometimes to be discerned through it, and is sometimes entirely obscured by it; of part of the *Serratus magnus* and *Superior oblique*, which it covers; and of the convex oblique ridges formed by the ribs with the intervening intercostal spaces. The anterior border of the muscle is the only part which gives a distinct surface form. This border may be traced, when the muscle is in action, as a rounded edge, starting from the crest of the ilium, and passing obliquely forward and upward to the posterior border of the axilla, where it combines with the *Teres major* in forming a thick rounded fold, the posterior boundary of the axillary space. The muscles in the second layer influence to a very considerable extent the surface form of the back of the neck and upper part of the trunk. The *Levator anguli scapulae* reveals itself as a prominent divergent line, running downward and outward, from the transverse processes of the upper cervical vertebræ to the angle of the scapula, covered over and toned down by the overlying *Trapezius*. The *Rhomboidei* produce, when in action, a vertical eminence between the vertebral border of the scapula and the vertebral furrow, varying in intensity according to the condition of contraction or relaxation of the *Trapezius* muscle, by which they are for the most part covered. The lowermost part of the *Rhomboideus major* is not covered by the *Trapezius*, and forms on the surface an oblique ridge running upward and inward from the inferior angle of the scapula. Of the muscles of the third layer of the back, the *Serratus posticus superior* does not in any way influence surface form. The *Serratus posticus inferior*, when in strong action, may occasionally be revealed as an elevation beneath the *Latissimus dorsi*. The *Splenii* by their divergence serve to broaden out the upper part of the back of the neck and produce a local fullness in this situation, but do not otherwise influence surface form. Beneath all these muscles those of the fourth layer—the *Erector spinae* and its continuations—influence the surface form in a decided manner. In the loins, the *Erector spinae*, bound down by the lumbar fascia, forms a rounded vertical eminence, which determines the depth of the vertebral furrow, and which below tapers to a point on the posterior surface of the sacrum and becomes lost there. In the back it forms a flattened plane which gradually becomes lost. In the neck the only part of this group of muscles which influences surface form is the *Trachelomastoid*, which produces a short convergent line across the upper part of the posterior triangle of the neck, appearing from under cover of the posterior border of the *Sternomastoid* and being lost below beneath the *Trapezius*.

Applied Anatomy.—In cases of tuberculous caries of the vertebral bodies, and in other diseases affecting the vertebral column, rigidity of the spinal muscles is one of the earliest and most constant symptoms. A child with commencing vertebral disease always maintains the affected portion of the column in a state of absolute rigidity, to prevent the inflamed structures from being moved against each other; this is one of the best examples of nature's method of producing rest of the affected part.

II. MUSCLES AND FASCIÆ OF THE THORAX.

The muscles belonging exclusively to this region are few in number. They are the

Intercostales externi.
Intercostales interni.
Infracostales.

Triangularis sterni.
Levatores costarum.
Diaphragm.

Intercostal Fascia.—A thin but firm layer of fascia covers the outer surface of the External intercostal and the inner surface of the Internal intercostal muscles; and a third layer, more delicate, is interposed between the two planes of muscle fibres. These are the *intercostal fasciæ*, *external*, *middle*, and *internal*; they are best marked in those situations where the muscle fibres are deficient, as between the External intercostal muscles and sternum, in front, and between the Internal intercostals and vertebral column, behind.

The **Intercostal muscles** (Figs. 321 and 349) are two thin planes of muscle and tendon fibres, placed one over the other. They fill up the intercostal spaces, and are directed obliquely between the margins of the adjacent ribs. They have received the name *external* and *internal* from the position they bear to each other. Between them in the grooved under surface of the rib run the intercostal vessels and nerve. The tendon fibres are longer and more numerous than the muscle fibres; hence the walls of the intercostal spaces possess very considerable strength, to which the crossing of the muscle fibres materially contributes.

The **External intercostals** (*mm. intercostales externi*) are *eleven* in number on each side. They extend from the tubercles of the ribs, *behind*, to the commencement of the cartilages of the ribs, *in front*, where they terminate in a thin membrane, the *anterior intercostal membrane*, which is continued forward to the sternum. They *arise* from the lower border of the rib above, and are *inserted* into the upper border of the rib below. In the two lowest spaces they extend to the ends of the cartilages, and in the upper two or three spaces they do not quite extend to the ends of the ribs. Their fibres are directed obliquely downward and forward, in a similar direction with those of the External oblique muscle of the abdomen. They are thicker than the Internal intercostals.

The **Internal intercostals** (*mm. intercostales interni*) are also *eleven* in number on each side. They commence anteriorly at the sternum in the interspaces between the cartilage of the true ribs, and from the anterior extremities of the cartilages of the false ribs, and extend backward as far as the angles of the ribs, whence they are continued to the vertebral column by a thin aponeurosis, the *posterior intercostal membrane*. They *arise* from the ridge on the inner surface of the rib above, as well as from the corresponding costal cartilage, and are *inserted* into the upper border of the rib below. Their fibres are directed obliquely downward and backward, passing in the opposite direction to the fibres of the External intercostal muscle.

The **Infracostales** (*mm. subcostales*) consist of muscular and aponeurotic fasciculi, which vary in number and length; they are placed on the inner surface of the ribs, where the Internal intercostal muscles cease; they *arise* from the inner surface of one rib, and are *inserted* into the inner surface of the first, second, or third rib below. Their direction, like the Internal intercostals, is usually oblique. They are most frequently found between the lower ribs.

The **Triangularis sterni** (*m. transversus thoracis*) (Fig. 314) is a thin plane consisting of muscle and tendon fibres, and is situated upon the inner wall of the front of the thorax. It *arises* from the lower third of the posterior surface of the sternum, from the posterior surface of the ensiform cartilage, and from the sternal ends of the costal cartilages of the three or four lower true ribs. Its fibres diverge upward and outward, to be *inserted* by digitations into the lower borders and inner surfaces of the costal cartilages of the second, third, fourth, fifth, and sixth ribs. The lowest fibres of this muscle are horizontal in their direction, and are continuous with those of the Transversalis; those which succeed are oblique, while the superior fibres are almost vertical. This muscle varies much in its attachment, not only in different bodies, but on opposite sides of the same body. The internal mammary artery runs between this muscle and the costal cartilages.

The **Levatores costarum** (*mm. levatores costarum*) (Fig. 313), *twelve* in number on each side, are small tendinous and fleshy bundles which *arise* from the extrem-

ities of the transverse processes of the seventh cervical and the eleven upper thoracic vertebræ. They pass obliquely downward and outward and are *inserted* into the upper border, between the tubercle and the angle, of the rib, immediately below its vertebræ of origin. Each of the Inferior levatores divides into two fasciculi, one of which is inserted as above described; the other fasciculus passes down to the second rib below its origin; thus, each of the lower ribs receives fibres from the transverse processes of two vertebræ.

Nerves.—The muscles of this group are supplied by the intercostal nerves.

FIG. 314.—Posterior surface of sternum and costal cartilages, showing Triangularis sterni muscle. (From a preparation in the Museum of the Royal College of Surgeons of England.)

The **Diaphragm** (*diaphragma*) (Figs. 315 and 316) is a thin, musculo-fibrous septum placed at the junction of the upper with the middle third of the trunk; it separates the thoracic from the abdominal cavity, its convex upper surface forming the floor of the former, and its concave under surface the roof of the latter. Its peripheral part consists of muscle fibres which *arise* from the internal circumference of the thoracic outlet, as well as from certain lumbar vertebræ, and pass upward and inward to converge to a central tendon. *Anteriorly*, the Diaphragm *arises* from the dorsal surface of the ensiform cartilage by two fleshy strips (*pars sternalis*); on either side, from the inner surfaces of the six lower costal cartilages (seventh to twelfth) (*pars costalis*), interdigitating with slips of origin of the Transversalis abdominis. *Behind*, it takes *origin* from certain

lumbar vertebræ by two **crura**; and from aponeurotic arches named the **arcuate ligaments** (*pars lumbalis*).

The **crura** are situated on the bodies of the lumbar vertebræ, on each side of the aorta. The crura, at their origin, are tendinous in structure; the *right* crus, larger and longer than the left, *arises* from the anterior surface of the bodies and articular disks of the four upper lumbar vertebræ; the *left* crus *arises* from the three upper lumbar vertebræ; both blend with the anterior common ligament of the vertebral column.

The tendinous portion of each crus passes forward and inward to meet the corresponding portion of the opposite side, thus forming the tendinous arch known as the **middle arcuate ligament**. From this arch diverging muscle fibres *arise*, the outermost portion of which is directed upward and outward to the central tendon; the innermost portion decussate in front of the aorta, diverge in order to surround the œsophagus, and likewise end in the central tendon. The fibres derived from the right crus are the more numerous and pass in front of those derived from the left.

Each crus, in its tendinous portion, is perforated by the great and lesser splanchnic nerves and sometimes the ascending lumbar radicle of the azygos veins.

The **internal arcuate ligament** (*arcus lumbocostalis medialis*) is a tendinous arch in the fascia covering the upper part of the Psoas magnus muscle, on each side of the vertebral column. This tendinous arch is connected mesad to the body of the first (or second) lumbar vertebræ, laterad to the front of the tip of the transverse process of the first (or second) lumbar vertebræ.

The **external arcuate ligament** (*arcus lumbocostalis lateralis*) is the thickened upper margin of the anterior lamella of the lumbar fascia; it arches across the upper part of the Quadratus lumborum from the front of the transverse process of the first (or second) lumbar vertebra to the apex and lower margin of the twelfth rib.

The fibres of the Diaphragm derived from these sources vary in length; those arising from the ensiform cartilage are short and occasionally aponeurotic, continuous with the posterior layer of the Rectus abdominis sheath. Those arising from the arcuate ligaments, and more especially those from the cartilages of the ribs at the side of the thorax, are longer, describe well-marked curves as they ascend, and finally converge to be *inserted* into the margin of the central tendon.

The **central tendon of the Diaphragm** (*centrum tendineum*) is a thin but strong tendinous aponeurosis, situated at the centre of the vault formed by the muscle, immediately below the pericardium, with which it is partly blended. It is shaped somewhat like a trefoil leaf, consisting of three divisions, or leaflets, separated from one another by slight indentations. The right leaflet is the largest; the middle one, directed toward the ensiform cartilage, the next in size; and the left, the smallest. In structure, the tendon is composed of several planes of fibres which intersect one another at various angles, and unite into straight or curved bundles—an arrangement which affords it additional strength.

The **openings** in the Diaphragm are three large and several smaller apertures. The former are the aortic, the œsophageal, and the opening for the inferior vena cava.

The **aortic opening** (*hiatus aorticus*) is the lowest and the most posterior of the three large apertures connected with this muscle, being at the level of the first lumbar vertebra. It is situated slightly to the left of the middle line, immediately in front of the bodies of the vertebræ; and is, therefore, *behind* the Diaphragm, not in it. It is an osseaponeurotic aperture, formed by a tendinous arch (middle arcuate ligament) thrown across the front of the bodies of the vertebræ, from the crus on one side to that on the other, and it transmits the aorta, the vena azygos

major, and the thoracic duct. Sometimes the vena azygos major is transmitted upward through the right crus. Occasionally some tendinous fibres are pro-

FIG. 315.—The Diaphragm, seen from above. (Poirier and Charpy.)

FIG. 316.—The Diaphragm, viewed from in front. (Testut.)

longed across the bodies of the vertebræ from the inner part of the lower end of the crura, pass behind the aorta, and thus convert the opening into a fibrous ring

The **œsophageal opening** (*hiatus œsophageus*) is situated at the level of the tenth thoracic vertebra; it is elliptical in form, oblique in direction, muscular in structure, and is formed by the decussating fibres of the two crura. It is placed above, and at the same time anterior, and a little to the left of the aortic opening. It transmits the œsophagus and vagus nerves and some small œsophageal arteries. The anterior margin of this aperture is occasionally tendinous, being formed by the margin of the central tendon. The posterior and lateral margins are thick and the gullet is in contact with them for about half an inch. The right margin of the œsophageal opening is particularly prominent and lies in the *œsophageal groove* on the posterior surface of the left lobe of the liver.

The **opening for the inferior vena cava** (*foramen venae cavae*) is the highest opening, being about on the level of the disk between the eighth and ninth thoracic vertebrae; it is quadrilateral in form, tendinous in structure, and is placed at the junction of the right and middle leaflets of the central tendon, its margins being adherent to the wall of the inferior vena cava.

FIG. 317.—The Diaphragm, viewed from below. (Testut.)

The **right crus** transmits the greater and lesser splanchnic nerves of the right side; the **left crus** transmits the greater and lesser splanchnic nerves of the left side, and the vena azygos minor (inferior). The gangliated cords of the sympathetic usually enter the abdominal cavity by passing behind the internal arcuate ligaments.

Serous Membranes.—The serous membranes in relation with the Diaphragm are four in number, three covering its upper or thoracic surface, and one its abdominal surface. The three serous membranes on its upper surface are the two pleuræ on either side and the pericardium, which covers the middle portion of the tendinous centre. The greater portion of the under surface of the Diaphragm is covered by the peritoneum.

Nerves.—The Diaphragm is supplied by the right and left phrenic nerves, derived from the anterior primary divisions of the third, fourth, and fifth cervical nerves. The nerve filaments which pass to the Diaphragm from the lower four intercostal nerves are sensor in function and supply only the peritoneum.

Actions.—Each External intercostal muscle elevates the rib below. Owing to the oblique axis of the costovertebral articulation, the curved obliquity of the ribs themselves, and the

angular arrangement of the lower costal cartilages, the sternum is lifted upward and forward, the ribs upward and slightly outward, and the diameters of the thorax are thus increased.

The action of the Internal intercostals is in dispute. Haller long ago taught that they act together with the External intercostals as inspiratory muscles. Investigators have since endeavored to show that they act as expiratory muscles.¹ Others believe that the Intercostal muscles contract simultaneously and serve merely as strong septal supports which prevent the intercostal spaces from being pushed out or drawn in during respiration. Masoin and Du Bois Reymond,² in experiments on animals, proved that the intercartilaginous portions of the Internal intercostals contracted synchronously with the Diaphragm.

The Diaphragm is the principal muscle of inspiration, and presents the form of a dome concave toward the abdomen. The central part of the dome is tendinous, and the pericardium is attached to its upper surface; the circumference is muscular. During inspiration the lowest ribs are fixed, and from these and the crura the muscle fibres contract and draw downward and forward the central tendon with the attached pericardium. In this movement the curvature of the Diaphragm is scarcely altered, the dome moving downward nearly parallel to its original position and pushing before it the abdominal viscera. The descent of the abdominal viscera is permitted by the elasticity of the abdominal wall, but the limit of this is soon reached. The central tendon applied to the abdominal viscera then becomes a fixed point for the action of the Diaphragm, the effect of which is to elevate the lower ribs and through them to push forward the sternum and the upper ribs. The right cupola of the Diaphragm, lying on the liver, has a greater resistance to overcome than the left, which lies over the stomach, but to compensate for this the right crus and the fibres of the right side generally are stronger than those of the left.

In all expulsive acts the Diaphragm is called into action to give additional power to each expulsive effort. Thus, before sneezing, coughing, laughing, crying, or vomiting, and previous to the expulsion of urine or feces, or of the fetus from the uterus, a deep inspiration takes place. The height of the Diaphragm is constantly varying during respiration; it also varies with the degree of distention of the stomach and intestines and with the size of the liver. After a forced expiration the right cupola is on a level in front with the fourth costal cartilage, at the side with the fifth, sixth, and seventh ribs, and behind with the eighth rib; the left cupola is a little lower than the right. Halls Dally states that the absolute range of movement between deep inspiration and deep expiration averages in the male and female 30 mm. on the right side and 28 mm. on the left; in quiet respiration the average movement is 12.5 mm. on the right side and 12 mm. on the left.³

Skiagraphy shows that the height of the Diaphragm in the thorax varies considerably with the position of the body. It stands highest when the body is horizontal and the patient on his back, and in this position it performs the largest respiratory excursions with normal breathing. When the body is erect the dome of the Diaphragm falls, and its respiratory movements become less. The dome falls still lower when the sitting posture is assumed, and in this position its respiratory excursions are least in extent. These facts may, perhaps, explain why it is that patients suffering from severe dyspnea are most comfortable and least short of breath when they sit up. When the body is horizontal and the patient on his side, the two halves of the Diaphragm do not behave alike. The uppermost half sinks to a level lower even than when the patient sits, and moves little with respiration; the lower half rises higher in the thorax than it does when the patient is supine, and its respiratory excursions are much increased. In unilateral disease of the pleura or lungs analogous interference with the position or movement of the Diaphragm can generally be observed skiagraphically.

It appears that the position of the Diaphragm in the thorax depends upon three main factors, viz.: (1) The elastic retraction of the lung tissue, tending to pull it upward; (2) the pressure exerted on its under surface by the viscera; this naturally tends to be a negative pressure, or a downward suction, when the patient sits or stands, and a positive or an upward pressure when he lies; (3) the intra-abdominal tension due to the abdominal muscles. These are in a state of contraction in the standing position and not in the sitting position; hence, the Diaphragm when the patient stands is pushed up higher than when he sits.

The Levatores costarum being inserted near the fulcra of the ribs can exert but little action on them; they act as rotators and lateral flexors of the vertebral column.

The Triangularis sterni draws down the costal cartilages, and is therefore a muscle of expiration.

Mechanism of Respiration.—The respiratory movements must be examined during (a) quiet respiration, and during (b) forced respiration.

³ Inquiry into the Physiological Mechanism of Respiration, *Journal of Anatomy and Physiology*, vol. xliii, 1908.

Quiet Respiration.—The first and second pairs of ribs are fixed by the Scaleni and by the resistance of the cervical structures; the last pair, and through it the eleventh pair, are fixed by the Quadratus lumborum muscles. The other ribs are elevated, so that the first two intercostal spaces are diminished while the other spaces are increased in width. It has already been shown (p. 285) that elevation of the third, fourth, fifth, and sixth ribs leads to an increase in the antero-posterior and transverse diameters of the thorax; the vertical diameter is increased by the descent of the diaphragmatic dome so that the lungs are expanded in all directions except backward and upward. Elevation of the eighth, ninth, and tenth ribs is accompanied by an outward and backward movement, leading to an increase in the transverse diameter of the upper part of the abdomen; the elasticity of the anterior abdominal wall allows a slight increase in the antero-posterior diameter of this part, and in this way the decrease in the vertical diameter of the abdomen is compensated and space provided for its displaced viscera. Expiration is effected by the elastic recoil of the abdominal walls and by the action of the abdominal muscles, which push back the viscera displaced downward by the Diaphragm.

Forced Respiration.—All the movements of quiet respiration are here carried out, but to a greater extent. In inspiration the shoulders and the vertebral borders of the scapulae are fixed and the limb muscles, Trapezius, Serratus magnus, Pectorals, and Latissimus dorsi, are called into play. The Scaleni are in stronger action, and the Sternomastoids also assist, when the head is fixed, by drawing up the sternum and by fixing the clavicles. The first rib is therefore no longer stationary, but, with the sternum, is raised; with it all the other ribs except the last are raised to a higher level. In conjunction with the increased descent of the Diaphragm this provides for a considerable augmentation of all the thoracic diameters. The anterior abdominal muscles come into action so that the umbilicus is drawn upward and backward, and this allows the Diaphragm to exert a more powerful influence on the lower ribs; the transverse diameter of the upper part of the abdomen is greatly increased and the subcostal angle is opened out. The deeper muscles of the back, *e. g.*, the Serrati postici superiores and the Erectores spinae, are also brought into action; the thoracic curve of the vertebral column is partially straightened, and the whole column, above the lower lumbar vertebrae, is drawn backward. This increases the antero-posterior diameters of the thorax and of the upper part of the abdomen and widens the intercostal spaces. Forced expiration is effected by the recoil of the abdominal walls, by the contraction of the antero-lateral muscles of the abdominal wall, and of the Serrati postici inferiores and Triangularis sterni.

Halls Dally (*op. cit.*) gives the following figures as representing the average changes which occur during deepest possible respiration. The manubrium moves 30 mm. in an upward, and 14 mm. in a forward direction; the width of the subcostal angle, at a level of 30 mm. below the articulation of the manubrium with the gladiolus, is increased by 26 mm.; the umbilicus is retracted and drawn upward for a distance of 13 mm.

III. MUSCLES OF THE ABDOMEN.

The muscles of the abdomen may be divided into two groups: (1) The antero-lateral muscles of the abdomen. (2) The posterior muscles of the abdomen.

1. The Antero-lateral Muscles of the Abdomen.

The muscles of this group are the

External oblique.
Internal oblique.

Transversalis.
Rectus.

Pyramidalis.

Dissection (Fig. 318).—To dissect the abdominal muscles, make a vertical incision from the ensiform cartilage to the symphysis pubis; a second incision from the umbilicus obliquely upward and outward to the outer surface of the thorax, as high as the lower border of the fifth or sixth rib; and a third, commencing midway between the umbilicus and pubes, transversely outward to the anterior superior iliac spine, and along the crest of the ilium as far as its posterior third. Then reflect the three flaps included between these incisions from within outward, in the lines of direction of the muscle fibres. If necessary, the abdominal muscles may be made tense by inflating the peritoneal cavity through the umbilicus.

The **superficial fascia** of the abdomen consists, over the greater part of the abdominal wall, of a single layer of fascia, which contains a variable amount of fat; but as this layer approaches the groin it is easily divisible into two layers, between which are found the superficial vessels and nerves and the superficial inguinal lymph nodes. The **superficial layer of the superficial fascia** (*fascia of Camper*) is thick, areolar in texture, and contains in its meshes adipose tissue, the quantity of which varies in different subjects. Below, it passes over Poupart's ligament, and is continuous with the outer layer of the superficial fascia of the thigh. In the male this fascia is continued over the penis and outer surface of the cord to the scrotum, where it helps to form the **dartos**. As it passes to the scrotum it changes its character, becoming thin, destitute of adipose tissue, and of a pale reddish color, and in the scrotum it acquires some nonstriated muscle fibres. From the scrotum it may be traced backward to be continuous with the superficial fascia of the perineum. In the female this fascia is continued into the labia majora. The **deep layer of the superficial fascia** (*fascia of Scarpa*) is thinner and more membranous in character than the superficial layer, and contains a considerable quantity of yellow elastic fibres. In the middle line it is intimately adherent to the linea alba and to the symphysis pubis, and is prolonged, in the male, on to the dorsum of the penis, forming the **suspensory ligament of the penis**; above, it joins the superficial layer and is continuous with the superficial fascia over the rest of the trunk; below, it blends with the fascia lata of the thigh a little below Poupart's ligament; and below and internally it is continued over the penis and spermatic cord to the scrotum, where it helps to form the dartos. From the scrotum it may be traced backward to be continuous with the deep layer of the superficial fascia of the perineum (*fascia of Colles*). In the female it is continued into the labia majora.

The **deep fascia** invests the External oblique muscle, but is so thin over the aponeurosis of the muscle as to be scarcely recognizable.

The **External or Descending oblique muscle** (*m. obliquus externus abdominis*) (Fig. 319) is situated on the side and fore part of the abdomen; being the largest and the most superficial of the three flat muscles in this region. It is broad, thin, and irregularly quadrilateral, its muscular portion occupying the side, its aponeurosis the anterior wall, of the abdomen. It *arises*, by eight fleshy digitations, from the external surface and lower borders of the eight inferior ribs; these digitations are arranged in an oblique line running downward and backward; the upper ones being attached close to the cartilages of the corresponding ribs; the lowest, to the apex of the cartilage of the last rib; the intermediate ones, to the ribs at some distance from their cartilages. The five superior serrations increase in size from above downward, and are received between corresponding processes of the Serratus magnus; the three lower ones diminish in size from above downward, receiving between them corresponding processes from the Latissimus dorsi. From these attachments, the fleshy fibres proceed in various directions. Those from the lowest ribs pass nearly vertically downward, to be *inserted* into the anterior half of the outer lip of the crest of the ilium; the middle and upper fibres, directed downward and forward, terminate in an aponeurosis, oppo-

FIG. 318.—Dissection of abdomen.

site a line drawn from the prominence of the ninth costal cartilage to the anterior superior spine of the ilium.

The **aponeurosis of the External oblique** is a thin, but strong membranous aponeurosis, the fibres of which are directed obliquely downward and inward. It is joined with that of the opposite muscle along the median line and covers the whole of the front of the abdomen; *above*, it is covered by and gives origin to the lower border of the Pectoralis major; *below*, some of its fibres are *inserted* into the symphy-

FIG. 319.—The External oblique muscle.

sis pubis, while others pass deeply through the middle line to be attached to the crest and iliopectineal line of the opposite side; these latter fibres are termed the **triangular fascia**. But the great majority of the fibres below are closely aggregated, and extend obliquely across from the anterior superior spine of the ilium to the spine of the os pubis and the iliopectineal line. In the *median line* it interlaces with the aponeurosis of the opposite muscle, forming the **linea alba**, which extends from the ensiform cartilage to the symphysis pubis.

That portion of the aponeurosis which extends between the anterior superior spine of the ilium and the spine of the os pubis is a broad band, folded inward, and continuous below with the fascia lata; it is called **Poupart's ligament**. The inner half inch of this ligament is reflected and attached to the subjacent pectineal line. This reflected part is called **Gimbernats's ligament**.

In the aponeurosis of the External oblique, immediately above the crest of the os pubis, is a triangular opening, the **external abdominal ring**, formed by a separation of the fibres of the aponeurosis in this situation.

FIG. 320.—Right external abdominal ring and saphenous opening in the male. (Spalteholz.)

Relations.—By its *superficial surface*, the External oblique muscle is in relation with the superficial fascia, superficial epigastric and circumflex iliac vessels, and some cutaneous nerves; by its *deep surface*, with the Internal oblique, the lower part of the eight inferior ribs, and Intercostal muscles, the Cremaster, the spermatic cord in the male, and round ligament in the female. Its *posterior border*, extending from the last rib to the crest of the ilium, is fleshy throughout and free; it is occasionally overlapped by the Latissimus dorsi, though generally a triangular interval exists between the two muscles near the crest of the ilium, in which is seen a portion of the Internal oblique. This triangle, **Petit's triangle** (*trigonum lumbale*) is therefore bounded in *front* by the External oblique, *behind* by the Latissimus dorsi, *below* by the crest of the ilium, and its floor is formed by the Internal oblique muscle (Fig. 319).

The following parts of the aponeurosis of the External oblique muscle require to be further described:

External Abdominal Ring.	Intercolumnar Fibres and Fascia.
Poupart's Ligament.	Gimbernats's Ligament.
Triangular Fascia of the Abdomen.	

The External Abdominal Ring (*annulus inguinalis subcutaneus*) (Figs. 320 and 323).—Just above and to the outer side of the crest of the os pubis an interval known as the **external abdominal ring** is seen in the aponeurosis of the External

oblique muscle. This opening is oblique in direction, corresponding with the course of the fibres of the aponeurosis, is somewhat triangular in form, and usually measures about an inch (2.5 cm.) from base to apex and about half an inch (1.25 cm.) transversely. It gives passage to the spermatic cord in the male and to the round ligament in the female. It is bounded *below* by the crest of the os pubis; *above*, by a series of curved fibres, the *external spermatic* or the *intercolumnar fibres* which pass across the upper angle of the ring, thus increasing its strength; and on *each side*, by the margins of the opening in the aponeurosis, which are called the *columns* or *pillars of the ring*.

The **external pillar** (*crus inferius*) is inferior from the obliquity of its direction. It is stronger than the internal pillar; it is formed by that portion of Poupart's ligament which is inserted into the spine of the os pubis; it is curved so as to form a kind of groove, upon which the spermatic cord rests.

The **internal pillar** (*crus superius*), a broad, thin, flat band, is formed by the fibres of the aponeurosis which are inserted into the symphysis pubis.

The **intercolumnar fibres** (*fibrae intercrurales*) (Fig. 320) are a series of curved tendinous fibres, which arch across the lower part of the aponeurosis of the External oblique. They have received their name from stretching across between the two pillars of the external ring, describing a curve with the concavity downward. They are much thicker and stronger at the outer margin of the external ring, where they are connected to the outer third of Poupart's ligament, than internally, where they are inserted into the linea alba. They are more strongly developed in the male than in the female. The intercolumnar fibres increase the strength of the lower part of the aponeurosis, and prevent the divergence of the pillars from each other.

These intercolumnar fibres as they pass across the external abdominal ring are themselves connected together by delicate fibrous tissue, thus forming a fascia, the **intercolumnar fascia** or the **external spermatic fascia**, which, as it is attached to the pillars of the ring, covers it in. This intercolumnar fascia is continued down as a tubular prolongation around the outer surface of the cord and testis or of the round ligament, and encloses them in a distinct sheath.

Applied Anatomy.—The sac of an inguinal hernia, in passing through the external abdominal ring, receives an investment from the intercolumnar fascia. If the finger is introduced a short distance into the external abdominal ring and the limb is then extended and rotated outward, the aponeurosis of the External oblique, together with the iliac portion of the fascia lata, will be felt to become tense, and the external ring much contracted; if the limb is, on the contrary, flexed upon the pelvis and rotated inward, this aponeurosis will become lax and the external abdominal ring sufficiently enlarged to admit the finger with comparative ease; hence the patient should always be put in the latter position when the taxis is applied for the reduction of an inguinal hernia in order that the abdominal walls may be relaxed as much as possible.

Poupart's Ligament (*ligamentum inguinale*).—The portion of Poupart's ligament in front of the crural ring is called the **superficial femoral arch**. Poupart's ligament is the lower border of the aponeurosis of the External oblique muscle, and extends from the anterior superior spine of the ilium to the pubic spine. From this latter point it is reflected to the iliopectineal line for about half an inch, thus forming **Gimbernat's ligament**. Its general direction is curved downward toward the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction and gives partial origin to the Internal oblique and Transversalis muscles. Its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord. Nearly the whole of the space included between the femoral arch and the innominate bone is filled in by the parts which descend from the abdomen into the thigh (Fig. 328). These will be referred to again on a subsequent page.

Gimbernat's ligament (*ligamentum lacunare*) (Figs. 320 and 328) is that part of Poupart's ligament which is reflected to the iliopectineal line. It is about half an inch in length, more prominent in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form with the base directed outward. Its *base*, or outer margin, is concave, thin, and sharp, and lies in contact with the crural sheath, forming the inner boundary of the **femoral or crural ring** (*annulus femoralis*). Its *apex* corresponds to the spine of the os pubis. Its *deep margin* is attached to the iliopectineal line, and is continuous with the pubic portion of the fascia lata. Its *superficial margin* is continuous with Poupart's ligament. Its *surfaces* are directed upward and downward.

Triangular Fascia (*ligamentum inguinale reflexum*).—The triangular fascia of the abdomen is a triangular layer of tendinous fibres, which comes from the aponeurosis of the opposite External oblique, and is attached by its *apex* to the iliopectineal line, where it is continuous with Gimbernat's ligament. It lies beneath the spermatic cord, behind the inner pillar of the external abdominal ring, and in front of the conjoined tendon.

Ligament of Cooper (Fig. 330).—This is a strong ligamentous band, which was first described by Sir Astley Cooper. It extends upward and backward from the base of Gimbernat's ligament along the iliopectineal line, to which it is attached. It is strengthened by the fascia transversalis, by the iliopectineal aponeurosis, and by a lateral expansion from the lower attachment of the linea alba (*admiculum lineae albae*).

Dissection.—Detach the External oblique by dividing it across, just in front of its attachment to the ribs, as far as its posterior border, and separate it below from the crest of the ilium as far as the anterior superior spine; then separate the muscle carefully from the Internal oblique, which lies beneath, and turn it toward the opposite side.

The **Internal or Ascending oblique muscle** (*m. obliquus internus abdominis*) (Fig. 321), thinner and smaller than the preceding, beneath which it lies, is of an irregularly quadrilateral form, and is situated at the side and fore part of the abdomen. It *arises*, by fleshy fibres, from the outer half of Poupart's ligament, to the groove on the upper surface of which it is attached; from the anterior two-thirds of the middle lip of the crest of the ilium, and from the posterior lamella of the lumbar fascia (Fig. 327). From this origin the fibres diverge; those from Poupart's ligament, few in number and paler in color than the rest, arch downward and inward across the spermatic cord in the male and across the round ligament in the female, and, becoming tendinous, are *inserted*, conjointly with those of the Transversalis, into the crest of the os pubis and iliopectineal line, to the extent of half an inch or more, forming what is known as the conjoined tendon of the Internal oblique and Transversalis. The fibres from the anterior third of the iliac origin are horizontal in their direction, and, becoming tendinous along the lower fourth of the linea semilunaris, pass in front of the Rectus muscle to be *inserted* into the linea alba; those which arise from the middle third of the origin from the crest of the ilium pass obliquely upward and inward, and terminate in an aponeurosis which divides at the outer border of the Rectus muscle into two lamellæ (Fig. 328), and are continued forward, in front and behind this muscle, to be *inserted* into the linea alba. The posterior lamella is also connected to the cartilages of the seventh, eighth, and ninth ribs; the fibres arising most posteriorly pass almost vertically upward, to be *inserted* into the lower borders of the cartilages of the three lower ribs, and are continuous with the Internal intercostal muscles. The lower fibres of this muscle are continuous with the Cremaster.

The **aponeurosis of the Internal oblique** is continued forward to the middle of the abdomen, where it joins with the aponeurosis of the opposite muscle at the linea alba, and extends from the costal arch to the os pubis. At the outer margin of the Rectus muscle this aponeurosis, for the upper three-fourths of its extent,

FIG. 321.—The Internal oblique muscle.

FIG. 322.—The deep epigastric artery and veins, ligament of Henle and ligament of Hesselbach, seen from in front. (Modified from Braune.)

divides into two lamellæ, which pass, one in front and the other behind the muscle, enclosing it in a kind of sheath, and reuniting on its inner border at the linea alba; the anterior layer is blended with the aponeurosis of the External oblique muscle; the posterior layer with that of the Transversalis. Along the lower fourth the aponeurosis passes altogether in front of the Rectus without any separation. Where the aponeurosis ceases to split, and passes altogether in front of the Rectus muscle, a deficiency is left in the sheath of the Rectus behind; this is marked above by a sharp lunated margin which has its concavity downward, and is known as the **semilunar fold of Douglas** (*linea semicircularis*) (Fig. 325).

Relations.—By its *superficial surface* the Internal oblique is in relation with the External oblique, Latissimus dorsi, spermatic cord, and external ring; by its *deep surface*, with the Transversalis muscle, the lower intercostal vessels and nerves, the iliohypogastric and the ilioinguinal nerves. Near Poupart's ligament it lies on the fascia transversalis, internal ring, and spermatic cord. Its lower border forms the upper boundary of the inguinal canal.

FIG. 323.—Diagram of sheath of rectus.

FIG. 324.—Diagram of a transverse section through the anterior abdominal wall, below the semilunar fold of Douglas.

The **Cremaster muscle** (*m. cremaster*) (Fig. 321) is a thin layer of muscle, composed of a number of fasciculi which *arise* from the inner part of Poupart's ligament, where its fibres are continuous with those of the Internal oblique and also occasionally with the Transversalis. It passes along the outer side of the spermatic cord, descends with it through the external abdominal ring upon the front and sides of the cord, and forms a series of loops which differ in thickness and length in different subjects. Those at the upper part of the cord are exceedingly short, but they become in succession longer and longer, the longest reaching down as low as the testicle, where a few are *inserted* into the tunica vaginalis. These loops are united by areolar tissue, and form a thin covering, the **cremasteric fascia**, over the cord and testis. The fibres of this muscle ascend along the inner side of the cord, and are *inserted* by a small pointed tendon into the crest of the os pubis and in front of the sheath of the Rectus muscle.

It will be observed that the origin and insertion of the Cremaster is precisely similar to that of the lower fibres of the Internal oblique. This fact affords an easy explanation of the manner in which the testicle and cord are invested by this muscle. At an early period of fetal life the testis is placed at the lower and back part of the abdominal cavity, but during its descent toward the scrotum, which takes place before birth, it passes beneath the arched fibres of the Internal oblique. As the testis and cord go to their destination in the scrotum they pass beneath this

muscle and carry with them and retain fibres derived from its lower part. It occasionally happens that the loops of the Cremaster surround the cord, some lying behind as well as in front. It is probable that under these circumstances the testis, in its descent, passed through instead of beneath the fibres of the Internal oblique.

In the descent of an oblique inguinal hernia, which takes the same course as the spermatic cord, the Cremaster muscle forms one of its coverings. This muscle becomes largely developed in cases of hydrocele and large old scrotal hernia. The Cremaster muscle is found only in the

FIG. 325.—The muscles of the abdomen, showing the semilunar fold of Douglas. Viewed from in front. (Spalteholz.)

male, but almost constantly in the female a few muscle fibres may be seen on the surface of the round ligament which correspond to this muscle, and in cases of oblique inguinal hernia in the female a considerable amount of muscle tissue may be found covering the sac.

Relations.—By its *superficial surface*, with the External oblique, Latissimus dorsi, spermatic cord, and external ring; by its *deep surface*, with the Transversalis muscle, the lower intercostal

vessels and nerves, the iliohypogastric and the ilioinguinal nerves. Near Poupart's ligament the Cremaster lies on the fascia transversalis, internal ring, and spermatic cord. Its lower border forms the upper boundary of the spermatic canal.

Dissection.—Detach the Internal oblique in order to expose the Transversalis beneath. This may be effected by dividing the muscle, *above*, at its attachment to the ribs; *below*, at its connection with Poupart's ligament and the crest of the ilium; and *behind*, by a vertical incision extending from the last rib to the crest of the ilium. The muscle should previously be made

FIG. 326.—The Transversalis, Rectus, and Pyramidalis muscles.

tense by drawing upon it with the fingers of the left hand, and if its division be carefully effected, the cellular interval between it and the Transversalis, as well as the direction of the fibres of the latter muscle, will afford a clear guide to their separation; along the crest of the ilium the circumflex iliac vessels are interposed between them, and form an important guide in separating them. The muscle should then be thrown inward toward the linea alba.

The **Transversalis muscle** (*m. transversus abdominis*) (Fig. 326), so called from the direction of its fibres, is the deepest flat muscle of the abdominal wall,

being placed immediately beneath the Internal oblique. It *arises* by fleshy fibres from the outer third of Poupart's ligament; from the inner lip of the crest of the ilium for its anterior three-fourths; from the inner surface of the cartilages of the six lower ribs, interdigitating with the Diaphragm; and from the lumbar fascia (Fig. 327), which may be regarded as the posterior aponeurosis of the muscle. The muscle terminates in front in a broad aponeurosis, the lower fibres of which curve downward and inward, and are *inserted*, together with those of the Internal oblique, on the crest of the os pubis and iliopectineal line, thus forming what is known as the conjoined tendon of the Internal oblique and Transversalis muscles. Throughout the rest of its extent the aponeurosis passes horizontally inward, and is *inserted* into the linea alba, its upper three-fourths passing behind the Rectus abdominis muscle, blending with the posterior lamella of the Internal oblique; its lower fourth passing in front of the Rectus.

The **conjoined tendon** of the Internal oblique and Transversalis is chiefly formed by the lower part of the tendon of the Transversalis, and is *inserted* into the crest of the os pubis and iliopectineal line, immediately behind the external abdominal ring, thus serving to protect what would otherwise be a weak point in the abdominal wall. The conjoined tendon is sometimes divided into an outer and an inner portion—the *former* termed the **ligament of Hesselbach**, the *latter*, the **ligament of Henle** (Fig. 322).

Relations.—By its *superficial surface*, with the Internal oblique, the lower intercostal nerves, and the inner surface of the cartilages of the lower ribs; by its *deep surface*, with the fascia transversalis, which separates it from the peritoneum. Its lower border forms the upper boundary of the inguinal canal.

Dissection.—To expose the Rectus abdominis muscle, open its sheath by a vertical incision extending from the costal arch to the os pubis, and then reflect the two portions from the surface of the muscle, which is easily done, excepting at the lineae transversae, where so close an adhesion exists that the greatest care is requisite in separating them. Now raise the outer edge of the muscle, in order to examine the posterior layer of the sheath. By dividing the muscle in the centre, and turning its lower part downward, the point where the posterior wall of the sheath terminates in a thin curved margin will be seen.

The **Rectus abdominis** (*m. rectus abdominis*) (Figs. 325 and 326) is a long flat muscle, which extends along the whole length of the front of the abdomen, being separated from its fellow of the opposite side by the linea alba. It is much broader, but thinner, above than below, and *arises* by two tendons; the external or larger is attached to the crest of the os pubis, the internal, smaller portion interlaces with its fellow of the opposite side, and is connected with the ligaments covering the front of the symphysis pubis. The fibres ascend, and the muscle is *inserted* by three portions of unequal size into the cartilages of the fifth, sixth, and seventh ribs. The longest portion attached principally to the cartilage of the fifth rib, usually has some fibres of insertion into the anterior extremity of the rib itself. Some fibres are occasionally connected with the costoxiphoid ligaments and side of the ensiform cartilage.

The Rectus muscle is traversed by tendinous intersections, three in number, which have received the name of **lineae transversae** (*inscriptiones tendineae*). One of these is usually situated opposite the umbilicus, and two above that point; of the latter, one corresponds to the extremity of the ensiform cartilage, and the other to the interval between the ensiform cartilage and the umbilicus. These intersections pass transversely or obliquely across the muscle in a zigzag course; they rarely extend completely through its substance, sometimes they pass only half-way across it, and are intimately adherent in front to the sheath in which the muscle is enclosed. Sometimes one or two additional lines may be seen, one usually below the umbilicus; the position of the other, when it exists, is variable. These additional lines are for the most part incomplete.

The Rectus is enclosed in a sheath, the **rectus sheath** (*vagina m. recti abdominis*) (Figs. 327 and 328), formed by the aponeurosis of the Oblique and Transversalis

FIG. 327.—A transverse section of the abdomen in the lumbar region.

muscles, which are arranged in the following manner. When the aponeurosis of the Internal oblique arrives at the outer margin of the Rectus it divides into two

FIG. 328.—Transition of the tendon of the right internal oblique into the sheath of the rectus. (Spalteholz.)

lamellæ, one of which passes in *front* of the Rectus, blending with the aponeurosis of the External oblique; the other, *behind* it, blending with the aponeurosis of the

Transversalis; and these, joining again at its inner border, are inserted into the linea alba. This arrangement of the aponeuroses exists along the upper three-fourths of the muscle; at the commencement of the lower fourth, the posterior wall of the sheath terminates in a thin curved margin, the **semilunar fold of Douglas** (*linea semicircularis*) (Fig. 325), the concavity of which looks downward toward the pubes; the aponeuroses of all three muscles pass in front of the Rectus without any separation. A very thin aponeurotic layer does pass behind the lower one-fourth of the muscle, but it is trivial as compared with the thickness of the layer behind the upper three-fourths of the muscle. This sudden thinning causes the semilunar fold of Douglas. The extremities of the fold of Douglas descend as pillars to the os pubis. The inner pillar is attached to the symphysis pubis; the outer pillar passes downward as a distinct band on the inner side of the internal abdominal ring to join with the outer fibres of the conjoined tendon, and assist in forming the **ligament of Hesselbach** (*ligamentum interfoveolare*) (Fig. 322). There its fibres divide into two sets, internal and external; the internal fibres are attached to the ascending ramus of the os pubis; the external fibres pass to the psoas fascia, to the deep surface of Poupart's ligament, and to the tendon of the Transversalis on the outer side of the ring. The Rectus muscle, in the situation where its sheath is deficient, is separated from the peritoneum by the transversalis fascia. Since the tendon of the Internal oblique and the Transversalis only reach as high as the costal margin, it follows that above this level the sheath of the Rectus is also deficient behind, the muscle resting directly on the cartilages of the ribs, being covered merely by the aponeurotic tendon of the External oblique. The convex outer border of the Rectus muscle corresponds to the linea semilunaris.

The **Pyramidalis** (*m. pyramidalis*) is a small muscle, triangular in shape, placed at the lower part of the abdomen, in front of the Rectus, and is contained in the same sheath. It *arises* by tendinous fibres from the front of the os pubis and the anterior pubic ligament; the fleshy portion of the muscle passes upward, diminishing in size as it ascends, and terminates by a pointed extremity, which is *inserted* into the linea alba, midway between the umbilicus and the os pubis. This muscle is sometimes found wanting on one or both sides; the lower end of the Rectus then becomes proportionately increased in size. Occasionally it has been found double on one side, or the muscles of the two sides are of unequal size. Its length varies slightly.

Besides the Rectus and Pyramidalis muscles, the sheath of the Rectus contains the superior and deep epigastric arteries, the terminations of the lumbar arteries and of the lower intercostal arteries and nerves.

Nerves.—The abdominal muscles are supplied by the lower intercostal nerves. The Transversalis and Internal oblique also receive filaments from the hypogastric branch of the iliohypogastric and sometimes from the ilioinguinal. The Cremaster is supplied by the genital branch of the genitofemoral. The Pyramidalis is supplied by the twelfth thoracic nerve.

The **linea alba** (Figs. 326 and 327) is a tendinous raphé seen along the middle line of the abdomen, extending from the ensiform cartilage to the superior pubic ligament, to which it is attached. It is placed between the inner borders of the Recti muscles, and is formed by the blending of the aponeuroses of the Obliqui and Transversales muscles. It is narrow below, corresponding to the narrow interval existing between the Recti, but broader above, as these muscles diverge from one another in their ascent; it becomes of considerable breadth when there is great distention of the abdomen from pregnancy or from ascites. It presents numerous apertures for the passage of vessels and nerves; the largest of these is the **umbilicus** (Fig. 329). The umbilicus is a fibrous ring formed by the fibres of the aponeurosis of the linea alba; in the fetus it transmits the umbilical vein, the two hypogastric arteries, the allantoic duct, and the vitello-intestinal duct; but in the adult the aperture is filled with scar tissue and is obliterated; the resulting cicatrix is stronger than the neighboring parts; hence umbilical hernia occurs in the adult *near* the umbilicus, while in the fetus it occurs *at* the umbilicus. The remains of the fetal structures are cord-like in character; and they diverge from the umbilicus within the abdomen.

The remains of the umbilical vein constitute the round ligament of the liver, and this cord passes upward (Fig. 329). The remains of the hypogastric arteries pass downward (Fig. 329). The remains of the allantois become the urachus, which passes to the summit of the bladder (Fig. 329). The depression of the umbilicus is created by the urachus.

The **lineae semilunares** (Figs 319 and 325) are two curved tendinous lines placed one on each side of the linea alba. Each corresponds with the outer border of the Rectus muscle, and each extends from the cartilage of the ninth rib to the pubic spine, and is formed by the aponeurosis of the Internal oblique at its point of division to enclose the Rectus, where it is reinforced in front by the External oblique and behind by the Transversalis.

Actions.—The abdominal muscles perform a three-fold action:

When the pelvis and thorax are fixed, they compress the abdominal viscera, by constricting the cavity of the abdomen, in which action they are materially assisted by the descent of the Diaphragm. By these means assistance is given in expelling the fetus from the uterus, the feces from the rectum, the urine from the bladder, and the contents of the stomach in vomiting.

If the pelvis and vertebral column be fixed, these muscles compress the lower part of the thorax, materially assisting expiration. If the pelvis alone is fixed, the thorax is bent directly forward when the muscles of both sides act, or to either side when those of the two sides act alternately, rotation of the trunk at the same time taking place to the opposite side.

If the thorax be fixed, these muscles, acting together, draw the pelvis upward, as in climbing, or, acting singly, they draw the pelvis upward, and bend the vertebral column to one side or the other. The Recti muscles, acting from below, depress the thorax, and consequently flex the vertebral column; when acting from above, they flex the pelvis upon the vertebral column. The Pyramidales are tensors of the linea alba.

The **fascia transversalis** (*fascia transversalis*) is a thin aponeurotic membrane which lies between the deep surface of the Transversalis muscle and the extra-peritoneal fat. It forms part of the general layer of fascia which lines the interior of the abdominal and pelvic cavities, and is directly continuous with the iliac and pelvic fasciæ. In the inguinal region the transversalis fascia is thick and dense in structure, and joined by fibres from the aponeurosis of the Transversalis muscle, but it becomes thin and cellular as it ascends to the Diaphragm, and blends with the fascia covering this muscle. In *front*, it unites across the middle line with the fascia on the opposite side of the body, and *behind* it becomes lost in the fat which covers the posterior surfaces of the kidneys. *Below*, it has the following attachments: Posteriorly, it is connected to the whole length of the crest of the ilium, between the attachments of the Transversalis and Iliacus muscles; between the anterior superior spine of the ilium and the femoral vessels it is connected to the posterior margin of Poupart's ligament, and is there continuous with the iliac fascia. Internal to the femoral vessels it is thin and attached to the pubis and to the iliopectineal line, behind the conjoined tendon, with which it is united; and, corresponding to the point where the femoral vessels pass into the thigh, this fascia descends in front of them, and forms the anterior wall of the femoral sheath. Beneath Poupart's ligament the transversalis fascia is strengthened by a band of fibrous tissue, which is only loosely connected to Poupart's ligament, and is specialized as the **deep femoral arch**. The spermatic cord in the male and the round ligament in the female pass through this fascia; the point where they pass through is called the **internal abdominal ring**. This opening is not visible externally, owing to a prolongation of the transversalis fascia on these structures, which forms the **infundibuliform fascia**.

FIG. 329.—The umbilicus of the fetus seen from within the abdomen. (Poirier and Charpy.)

The **internal or deep abdominal ring** (*annulus inguinalis abdominis*) (Figs. 322 and 330) is situated in the transversalis fascia, midway between the anterior superior spine of the ilium and the symphysis pubis, and about half an inch above Poupart's ligament. It is of an oval form, the extremities of the oval directed upward and downward, varies in size in different subjects, and is much larger in the male than in the female. The internal ring is bounded, *above* and *externally*, by the arched fibres of the Transversalis; *below* and *internally*, by the deep epigastric vessels. It transmits the spermatic cord in the male and the round ligament in the female. From its circumference a thin funnel-shaped membrane, the **infundibuliform or internal spermatic fascia**, is continued around the cord and testis, enclosing them in a distinct covering.

FIG. 330.—The relation of the femoral and internal abdominal rings, seen from within the abdomen after removal of the peritoneum. (Poirier and Charpy.)

When the sac of an oblique inguinal hernia passes through the internal or deep abdominal ring, the infundibuliform process of the transversalis fascia forms one of its coverings.

The Inguinal or Spermatic Canal (*canalis inguinalis*) (Figs. 331 and 332).—The inguinal or spermatic canal contains the **spermatic cord** (*funiculus spermaticus*) in the male and the **round ligament** (*ligamentum teres uteri*) in the female. It is an oblique canal about an inch and a half in length, directed downward and inward, and placed parallel to and a little above Poupart's ligament. It commences above at the internal or deep abdominal ring, which is the point where the cord enters the spermatic canal, and terminates below at the external ring. It is bounded in *front* by the aponeurosis of the External oblique throughout its whole length, and by the Internal oblique for its outer third; *behind*, from within outward, by the triangular fascia (when this is present), the conjoined tendon, and the transversalis fascia; *below*, by Gimbernat's ligament, and by the union of the fascia transversalis with Poupart's ligament. The deep epigastric artery passes upward and inward behind the canal lying close to the inner side of the internal abdominal ring (Fig. 322). The interval between this artery and the outer edge of the Rectus abdominis is named **Hesselbach's triangle**, the base of which is formed by Poupart's ligament.

FIG. 331.—The right inguinal canal in the male, second layer, viewed from in front. (The first layer is shown in Fig. 320.) (Spalteholz.)

FIG. 332.—The right inguinal canal in the male, third layer, viewed from in front. (Spalteholz.)

That form of protrusion in which the intestine follows the course of the spermatic cord along the spermatic canal is called oblique inguinal hernia.

Surface Form.—The only two muscles of this group which have any considerable influence on surface form are the External oblique and the Rectus muscles of the abdomen. With regard to the External oblique, the upper digitations of its origin from the ribs are well marked, and are intermingled with the serrations of the Serratus magnus; the lower digitations are not visible, as they are covered by the thick border of the Latissimus dorsi. The attachment of the External oblique to the crest of the ilium, in conjunction with the Internal oblique, forms a thick oblique roll, which determines the *iliac furrow*. Sometimes on the front of the lateral region of the abdomen an undulating outline marks the spot where the muscle fibres terminate and the aponeurosis commences. The outer border of the Rectus is defined by the *linea semilunaris*, which may be exactly located by putting the muscle into action. It corresponds with a curved line, with its convexity outward, drawn from the end of the cartilage of the ninth rib to the spine of the os pubis, so that the centre of the line, at or near the umbilicus, is three inches from the median line. The inner border of the Rectus corresponds to the *linea alba*, marked on the surface of the body by a groove, the **abdominal furrow**, which extends from the infrasternal fossa to, or to a little below, the umbilicus, where it gradually becomes lost. The surface of the Rectus presents three transverse furrows, the *lineæ transversæ*. The upper two of these, one opposite or a little below the tip of the ensiform cartilage, and another, midway between this point and the umbilicus, are usually well marked; the third, opposite the umbilicus, is not so distinct. The umbilicus, situated in the linea alba, varies very much in position as regards its level. It is always situated above a zone drawn around the body opposite the highest point of the crest of the ilium, generally being from three-quarters of an inch to an inch above this line. It usually corresponds, therefore, to the articular disk between the third and fourth lumbar vertebræ.

2. The Posterior Muscles of the Abdomen.

Psoas magnus.

Psoas parvus.

Iliacus.

Quadratus lumborum.

The Psoas magnus, the Psoas parvus, and the Iliacus muscles, with the fascia covering them, will be described with the Muscles of the Lower Extremity.

The Fascia Covering the Quadratus Lumborum (Fig. 327).—This is the most anterior of the three layers of the lumbar fascia. It is a thin layer of fascia, which, passing over the anterior surface of the Quadratus lumborum, is attached, *internally*, to the bases of the transverse processes of the lumbar vertebræ; *below*, to the iliolumbar ligament; and *above*, to the apex and lower border of the last rib.

The portion of this fascia which extends from the transverse process of the first lumbar vertebra to the apex and lower border of the last rib constitutes the **ligamentum arcuatum externum**.

The **Quadratus lumborum** (*m. quadratus lumborum*) (Fig. 313) is situated in the lumbar region. It is irregularly quadrilateral in shape, and broader below than above. It *arises* by aponeurotic fibres from the iliolumbar ligament and the adjacent portion of the crest of the ilium for about two inches, and is *inserted* into the lower border of the last rib for about half its length, and by four small tendons, into the apices of the transverse processes of the four upper lumbar vertebræ. Occasionally a second portion of this muscle is found situated in front of the preceding. This *arises* from the upper borders of the transverse processes of three or four of the lower lumbar vertebræ, and is *inserted* into the lower margin of the last rib. The Quadratus lumborum is contained in a sheath formed by the anterior and middle lamellæ of the lumbar fasciæ.

Relations.—Its *deep surface* (or rather the fascia which covers its anterior surface) is in relation with the colon, the kidney, the Psoas muscle, and the Diaphragm. Between the fascia and the muscle are the last thoracic, iliohypogastric, and ilioinguinal nerves. Its *superficial surface* is in relation with the middle lamella of the lumbar fascia, which separates it from the

Erector spinae. The *Quadratus lumborum* extends, however, beyond the outer border of the *Erector spinae*.

Nerve-supply.—The anterior branches of the last thoracic and the first lumbar nerves; sometimes also a branch from the second lumbar nerve.

Actions.—The *Quadratus lumborum* draws down the last rib. It acts as a muscle of inspiration by helping to fix the origin of the *Diaphragm*. If the thorax and vertebral column are fixed, it may act upon the pelvis, raising it toward its own side when only one muscle is put in action; and when both muscles act together, either from below or above, they flex the trunk.

IV. MUSCLES AND FASCIÆ OF THE PELVIC OUTLET.

The **muscles** and **fasciæ** of the pelvic outlet are those structures which form the floor of the pelvis. **Perineum** is a term used to designate that segment of the structure lying dorsal to the pubic arch and subpubic ligament and ventral to a line drawn transversely, in front of the anus, between the anterior part of the tuberosity of the ischium of each side. The **ischiorectal space** is the name given to the segment dorsal to the line above mentioned and ventral to the tip of the coccyx. This space is bounded laterally by the *Gluteus maximus* muscle.

FIG. 333.—The perineum. The integument and superficial layer of superficial fascia reflected.

The **fascia** of the pelvic outlet is most easily understood if it is considered in the order of its dissection. Considered thus, it resolves itself into three strata—the superficial fascia, the triangular ligament, and the pelvic fascia. The *superficial fascia* is made up, as in other regions of the body, of a *superficial* and a *deep* layer. The fascia over the ischiorectal region is arranged in fatty layers, which fill the ischiorectal fossa on each side of the rectum and anus. In the region of the perineum the fascia requires fuller consideration; here it is definitely arranged into two layers—*superficial* and *deep*. The **superficial layer** is thick, loose, areolar in texture, and, except toward the scrotum, contains in its meshes

much adipose tissue, the amount of which varies in different subjects. In *front* this layer is continuous with the dartos of the scrotum, in the mid-line of which it dips deeply to form the scrotal septum. In the female this structure enters

FIG. 334.—The muscles of the male perineum, viewed from below. (Spalteholz.)

into the formation of the mons veneris and the labia majora. The superficial layer is continuous on either side with the fatty fascia on the inner side of the thighs. The **deep layer of the superficial fascia**, or the **fascia of Colles**, is thin, aponeurotic in structure, and of considerable strength. It serves to bind down the

muscle of the root of the penis. It is continuous with the dartos of the scrotum, with the fascia of the penis, and with Scarpa's fascia on the anterior surface of the abdomen; on *either side* it is firmly attached to the outer lip of the ischiopubic ramus. *Posteriorly* (dorsally) the deep layer curves around the superficial transverse perineal muscle to blend with the base of the triangular ligament. The *deep* (cephalic) surface of this fascia covers the superficial muscles and the superficial bloodvessels and nerves of the perineum. From its deep surface a septum which is incomplete in front is given off and divides the adjacent space in two.

The Central Tendinous Point of the Perineum.—This is a fibrous point in the middle line of the pelvic outlet, between the urethra and the rectum, and about half an inch in front of the anus. At this point four muscles converge and are attached—viz., the External sphincter ani, the Accelerator urinae, and the two Superficial transverse perineal; so that by the contraction of these muscles, which extend in opposite directions, it serves as a fixed point of support.

FIG. 335.—The superficial muscles and vessels of the perineum.

The Muscles of the Perineum in the Male (Figs. 333, 334, 335).

Superficial transverse perineal.
Accelerator urinae.

Erector penis.
Compressor urethrae.

The Superficial transverse perineal muscle (*m. transversus perinei superficialis*) is a narrow muscular slip, which passes more or less transversely across the pelvic outlet. It *arises* by a small tendon from the inner and fore part of the tuberosity of the ischium, and, passing inward, is *inserted* into the central tendinous point of the perineum, joining in this situation with the muscle of the opposite side, the External sphincter ani behind, and the Accelerator urinae in front. The base of the triangular ligament lies under cover of this muscle.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—By their contraction they serve to fix the central tendinous point of the perineum.

The **Accelerator urinae** (*m. bulbocavernosus*) is placed in the middle line of the perineum, immediately in front of the anus. It consists of two symmetrical

FIG. 336.—Triangular ligament or deep perineal fascia. On the left side the anterior layer has been removed.

FIG. 337.—A view of the position of the viscera at the outlet of the pelvis.

halves, united along the median line by a tendinous raphé. It arises from the central tendon of the perineum, and from the median raphé in front. From this

point its fibres diverge symmetrically; the most posterior form a thin layer, which is lost on the superficial surface of the triangular ligament; the middle fibres encircle the bulb and adjacent parts of the corpus spongiosum, and join with the fibres of the opposite side, on the upper part of the corpus spongiosum, in a strong aponeurosis. The anterior fibres, the longest and most distinct, spread out over the sides of the corpus cavernosum, and are *inserted* partly into that body, anterior to the Erector penis (occasionally extending to the os pubis), and partly terminate in a tendinous expansion, which covers the dorsal vessels of the penis. The latter fibres are best seen by dividing the muscle longitudinally, and dissecting it outward from the surface of the urethra. Many fibres of the External sphincter ani and of the Superficial transverse perineal muscles pass into this muscle.

Action.—This muscle serves to empty the canal of the urethra, after the bladder has expelled its contents; during the greater part of the act of micturition its fibres are relaxed, and it only comes into action at the end of the process. The middle fibres are supposed, by Krause, to assist in the erection of the corpus spongiosum, by compressing the erectile tissue of the bulb. The anterior fibres, on each side, according to Tyrrel, also contribute to the erection of the penis, as they are inserted into, and are continuous with, the fascia of the penis, and thus compress the dorsal vein during the contraction of the muscle.

The **Erector penis** (*m. ischiocavernosus*) covers part of the crus penis. It is an elongated muscle, broader in the middle than at either extremity, and situated on either side of the lateral boundary of the perineum. It *arises* by tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind the crus penis, from the surface of the crus, and from the adjacent portion of the ramus of the ischium. From these points fleshy fibres succeed, which end in an aponeurosis which is *inserted* into the sides and under surface of the crus penis.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—This muscle compresses the crus penis and retards the return of the blood through the veins, and thus serves to maintain the organ erect.

Between the muscles just examined a triangular space exists, bounded internally by the Accelerator urinae, externally by the Erector penis, and behind by the Transversus perinei superficialis. The floor of this space is formed by the triangular ligament of the perineum (deep perineal fascia), and running in it from behind forward (toward the pubis) are the superficial perineal vessels and nerves, the long pudendal nerve, and the transverse perineal artery, which courses along the posterior boundary of the space on the Superficial transverse perineal muscle.

The Muscles of the Perineum in the Female.

Superficial transverse perineal.
Sphincter vaginae.

Erector clitoridis.
Compressor urethrae.

The **Superficial transverse perineal** (*m. transversus perinei superficialis*) in the female is a narrow slip which passes more or less transversely across the back part of the perineal space. It *arises* by a small tendon from the inner and fore part of the tuberosity of the ischium, and, passing inward, is *inserted* into the central point of the perineum, joining in this situation with the muscle of the opposite side, the External sphincter ani behind, and the Sphincter vaginae in front.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—By their contraction these muscles serve to fix the central tendinous point of the perineum.

The **Sphincter vaginae** (*m. bulbocavernosus*) surrounds the orifice of the vagina; it is homologous with the Accelerator urinae in the male. It *arises* posteriorly from the central tendinous point of the perineum, where it blends with the External sphincter ani. Its fibres pass forward on each side of the vagina, where it covers the vaginal bulb, to be *inserted* into the corpora cavernosa of the clitoris; a fasciculus crosses over the body of the organ and compresses the dorsal vein.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—It diminishes the orifice of the vagina. The anterior fibres contribute to the erection of the clitoris, as they are inserted into and are continuous with the fascia of the clitoris and compress the dorsal vein during the contraction of the muscle.

FIG. 338.—The female perineum after removal of the skin and superficial fascia. (Bardeleben.)

The **Erector clitoridis** (*m. ischiocavernosus*) resembles the Erector penis in the male, but is smaller. It covers the unattached part of the crus clitoridis. It is an elongated muscle, broader at the middle than at either extremity, and situated on either side of the lateral boundary of the perineum. It *arises* by tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind the crus clitoridis from the surface of the crus, and from the adjacent portion of the ramus of the ischium. From these points fleshy fibres succeed, ending in an aponeurosis, which is *inserted* into the sides and under surface of the crus clitoridis.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—It compresses the crus clitoridis and retards the return of blood through the veins, and thus serves to maintain the organ erect.

The Triangular Ligament in the Male and in the Female.

The **triangular ligament** or the **deep perineal fascia** (*diaphragma urogenitale*) (Figs. 339 and 340) is stretched almost horizontally across the pubic arch, so as to close in the front part of the outlet of the pelvis. It consists of two dense musculomembranous laminae, which are united along their dorsal borders, but are separated ventrally by intervening structures. The **superficial layer** (*fascia diaphragmatis urogenitalis inferior*) is triangular in shape and about an inch and a half in depth. Its apex is directed forward, and is separated from the subpubic

FIG. 339.—The triangular ligament of the perineum.

ligament by an oval opening for the transmission of the dorsal vein of the penis. A strengthening band, the **transverse pelvic ligament** (*ligamentum transversum pelvis*), passes from one pubic bone to the other below the vein. The lateral margins of the inferior layer of the triangular ligament are attached on each side to the rami of the ischium and os pubis, above the crura penis. The fusion of the two leaves of the triangular ligament takes place under cover of the Superficial trans-

verse perineal muscles. The region of fusion of the two leaflets is called the **base**. The base is directed toward the rectum, and connected to the central tendinous point of the perineum. It is continuous with the deep layer of the superficial fascia behind the Superficial transverse perineal muscles, and with a thin fascia which covers the cutaneous surface of the Levator ani muscle, the **anal or ischio-rectal fascia**.

This layer of the triangular ligament is perforated, about an inch below the symphysis pubis, by the urethra, the aperture for which is circular in form; by the arteries to the bulb and by the ducts of Cowper's glands close to the urethral aperture; by the arteries to the corpora cavernosa—one on each side, close to the pubic arch and about half-way along the attached margin of the ligament; and by the dorsal arteries and nerves of the penis near the apex of the ligament. Its base is also perforated by the superficial perineal vessels and nerves, while between its apex and the subpubic ligament passes the dorsal vein of the penis.

FIG. 340.—The superficial layer of the triangular ligament. The Compressor urethrae muscle lies behind the superficial layer of the triangular ligament and is shown in the figure for convenience. (Poirier and Charpy.)

When this superficial layer of the triangular ligament is detached, the following structures will be seen between it and the deeper layer: The dorsal vein of the penis; the membranous portion of the urethra, and the Compressor urethrae muscle; Cowper's glands and their ducts; the pudic vessels and dorsal nerve of the penis; the artery and nerve of the bulb, and a plexus of veins.

The triangular ligament in the *female* is not so strong as in the male. It is divided in the middle line by the aperture of the vagina, with the external coat of which it becomes blended; between the vaginal orifice and the pubis it is perforated by the urethra. Its base is continuous, as in the male, with the deep layer of the superficial fascia surrounding the Transversus perinei muscles. Like the triangular ligament in the male, it consists of two layers, between which are to be found the following structures: The dorsal vein and nerves of the clitoris, a portion of the urethra and the Compressor urethrae muscle, the glands of Bartholin and their ducts, the pudic vessels, the arteries of the vestibular bulbs, and a plexus of veins. The deep layer of the triangular ligament is a part of the pelvic fascia, and is described on page 450.

The **Compressor or Constrictor urethrae** (*m. constrictor urethrae*) in the *male* surrounds the whole length of the membranous portion of the urethra, and is

contained between the two layers of the triangular ligament. It *arises*, by aponeurotic fibres, from the junction of the rami of the os pubis and ischium, to the extent of half or three-quarters of an inch—the point where the crura penis join the transverse ligament of the perineum and the layers of the triangular ligament; each segment of the muscle passes inward, and divides into two fasciculi, which *surround* the membranous urethra and *unite*, at the upper and lower surfaces of this tube, with the muscle of the opposite side by means of a tendinous raphé. This muscle is frequently discovered in two portions, an **anterior** and a **posterior**, separated by a distinct interval. In such cases the posterior fibres are called the **transversus perinei profundus**, and the anterior fibres are called the **sphincter urethrae membranaceae**. The Compressor urethrae in the *female* arises as in the male; passing mesally, likewise, it divides into two fasciculi; these latter, however, have not the same intimate functional relationship to the urethra as has the muscle of the male. One fasciculus passes ventrad of the urethra to blend with its opposite fellow; the posterior fascicle inserts itself into the lateral vaginal wall.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—The muscles of both sides act together as a sphincter, compressing the membranous portion of the urethra. During the transmission of fluid they, like the Acceleratores urinae, are relaxed, and come into action only at the end of the process, to eject the last drops of the fluid.

The Pelvic Fascia.

The **pelvic fascia** binds strongly together the pelvic structures, supports the bloodvessels, nerves, and lymphatics, and strengthens the floor of the cavity. *Above*, it is loosely connected to the back part of the iliopectineal line, and is continuous here with the iliac fascia. *Posteriorly*, over the sacrum, it is very

FIG. 341.—Pelvic fascia (semidiagrammatic).

thin and lies ventrad to the Piriformis muscle and to the sacral plexus of nerves. This part is often called the **fascia of the Piriformis**, and extends outward along the muscle into the gluteal region. At its sacral attachments around the margins of the sacral foramina it comes into intimate association with and en-

sheathes the nerves as they emerge from these foramina. Anterior to its iliopectineal attachment the pelvic fascia sinks in its attachment below the brim of the pelvis. It arches below the obturator vessels and nerves, completing the obturator canal, and at the front of the pelvis the line of attachment is depressed distally on the posterior surface of the os pubis, so that at the symphysis it lies just above the inferior border of this bone. From this line of attachment the posterior part is prolonged outward on the Obturator internus into the gluteal region. The middle portion descends on the visceral surface of the Obturator internus to become attached to the falciform process of the great sacrosacral ligament. Because of this relation with the Obturator internus this part is called the **Obturator fascia**. The part attached to the body of the pubis descends to be attached to the ischiopubic ramus, and here becomes blended with the base of the triangular ligament. From the ischiopubic ramus it is continued onward behind the Compressor

FIG. 342.—A transverse section of the pelvis, showing the pelvic fascia from behind.

urethrae muscle across the pubic arch, to be continuous with the fascia of the opposite side. Here it takes a special name, the **deep layer of the triangular ligament** (*fascia diaphragmatis urogenitalis superior*). This part of the fascia is perforated by the urethra; a portion of it turns backward around the anterior extremity of the Levator ani muscle to join the visceral layer next to be considered.

At the level of a line extending from the back part of the symphysis pubis to the spine of the ischium is a thick, whitish band termed the **white line** (*arcus tendineus*). Above this line the fascia lies in contact with the peritoneum and belongs to the pelvic cavity. Below this line the obturator fascia has to do with the ischio-rectal space. The pudic vessels and nerves cross this area enclosed in a special sheath (**Alcock's canal**). At the white line the obturator fascia gives off a special layer to the pelvic viscera (*fascia endopelvina*); where these two layers diverge partly arises the Levator ani. The visceral layer lies superior (cephalad) to the Levator ani. Traced forward it is seen to be attached to the posterior

surface of the body of the pubis three-fourths of an inch higher than the pelvic fascia. Traced internally it approaches the bladder and rectum; here it splits into several layers. The upper layer invests the bladder and constitutes the *lateral true ligament* of the bladder; another prolongation invests the seminal vesicle, passes between the bladder and rectum, being continuous with the same fascia on the opposite side; a third investment is also prolonged downward on the rectum within the insertion of the Levator ani muscle. In front of the bladder the fascia closely ensheathes the prostate gland and prostate plexus of veins, forming the capsule of the prostate. That portion of the fascia which is attached to the body of the pubis passes backward as a narrow cord-like band to the upper part of the prostate and upper part of the neck of the bladder; this is the *anterior true ligament* of the bladder, or *puboprostatic ligament*.

FIG. 343.—Side view of the pelvic viscera of the male subject, showing the pelvic and perineal fasciæ.

The **Levator ani** (Fig. 345) is a broad, thin muscle, situated on the side of the pelvis. It is attached to the inner surface of the side of the true pelvis, and descends to unite with its fellow of the opposite side. Together these structures form the greater part of the floor of the pelvic cavity. They support the viscera in this cavity and surround the various structures which pass through it. This muscle *arises*, in *front*, from the posterior surface of the body of the pubis on the outer side of the symphysis; *behind*, from the inner surface of the spine of the ischium; and *between* these two points, from the pelvic fascia. *Posteriorly*, this fascial origin corresponds, more or less closely, with the white line (page 450), but in front the muscle arises from the fascia at a varying distance above the white line, in some cases reaching nearly as high as the canal for the obturator vessels and nerve. The fibres pass downward to the middle line of the floor of the pelvis; the most posterior are *inserted* into the sides of the last two segments of the coccyx; those placed more anteriorly unite with the muscle of the opposite side, in a median

fibrous raphé (*anococcygeal raphé*), which extends between the coccyx and the margin of the anus. The middle fibres are *inserted* into the side of the rectum, blending with the fibres of the Sphincter muscles; lastly, the anterior fibres descend upon the side of the prostate gland to unite beneath it with the muscle of the opposite side, joining with the fibres of the External sphincter and Transversus perinei muscles at the central tendinous point of the perineum.

FIG. 344.—The right Levator ani in the male, viewed from the left. (Spalteholz.)

The anterior portion is occasionally separated from the rest of the muscle by connective tissue. From this circumstance, as well as from its peculiar relation with the prostate gland, descending by its side, and surrounding it as in a sling, it has been described by Santorini and others as a distinct muscle, under the name of *Levator prostatae*. In the female the anterior fibres of the Levator ani descend upon the side of the vagina.

Relations.—By its *deep, upper, or pelvic surface* the Levator ani is in relation with the pelvic fascia, which separates it from the bladder, prostate, rectum, and peritoneum. By its *superficial, lower, or perineal surface*, it forms the inner boundary of the ischiorectal fossa, and is covered by a thin layer of fascia, the *ischiorectal or anal fascia*, given off from the obturator fascia. Its *posterior border* is free and separated from the Coccygeus muscle by a cellular interspace. Its *anterior border* is separated from the muscle of the opposite side by a triangular space, through which the urethra, and in the female the vagina, pass from the pelvis.

The Levator ani may be divided into iliococcygeal and pubococcygeal parts.

The *Iliococcygeus* arises from the ischial spine and from the posterior part of the pelvic fascia, and is attached to the coccyx and anococcygeal raphe; it is usually thin, and may fail entirely, or be largely replaced by fibrous tissue. An accessory slip at its posterior part is sometimes named the *Iliosacralis*. The *Pubococcygeus* arises from the back of the pubis and from the anterior part of the pelvic fascia, and "is directed backward almost horizontally along the side of the anal canal toward the coccyx and sacrum, to which it finds attachment. Between the

FIG. 345.—The levator ani of the male, viewed from above. (Spalteholz.)

termination of the vertebral column and the anus the two pubococcygeal muscles come together and form a thick, fibromuscular layer lying on the raphe formed by the iliococcygei" (Thompson). The greater part of this muscle is inserted into the coccyx and into the last one or two pieces of the sacrum. This insertion into the vertebral column is, however, not admitted by all observers. The fibres which form a sling for the rectum are named the *Puborectalis* or *Sphincter recti*. They arise from the lower part of the symphysis pubis, and from the upper layer of the triangular ligament. They meet with the corresponding fibres of the opposite side around the lower part of the rectum, and form for it a strong sling.

Nerve-supply.—The Levator ani is supplied by a branch from the fourth sacral nerve and by a branch which is sometimes derived from the perineal, sometimes from the inferior hemorrhoidal division of the pudic nerve.

The **Coccygeus** (*m. coccygeus*) (Fig. 345) is situated behind and parallel with the preceding. It is a triangular plane of muscular and tendinous fibres, arising

by its apex from the spine of the ischium and lesser sacrosciatic ligament, and *inserted* by its base into the margin of the coccyx and into the side of the lower piece of the sacrum. It assists the Levator ani and Piriformis in closing in the back part of the outlet of the pelvis.

Nerve-supply.—The Coccygeus is supplied by a branch from the fourth and fifth sacral nerves.

Actions.—The Levatores ani constrict the lower end of the rectum and vagina. They elevate and invert the lower end of the rectum after it has been protruded and everted during the expulsion of the feces. The Coccygei muscles pull forward and support the coccyx, after it has been pressed backward during defecation or parturition. The Levatores ani and Coccygei together form a muscular diaphragm which supports the pelvic viscera.

Muscles of the Ischiorectal Region.

- Corrugator cutis ani.
- Internal sphincter ani.
- External sphincter ani.
- Levator ani (described on page 451).
- Coccygeus (described on page 453).

The Corrugator Cutis Ani.—Around the anus is a thin stratum of involuntary muscle fibre which radiates from the orifice. *Internally*, the fibres fade into the submucous tissue, while *externally* they blend with the true skin. By its contraction it raises the skin into ridges around the margin of the anus.

The **External sphincter ani** (*m. sphincter ani externus*) (Figs. 334, 335, 338, and 344) is a thin, flat plane of muscle fibre, elliptical in shape and intimately adherent to the integument surrounding the margin of the anus. It measures about three or four inches in length from its anterior to its posterior extremity, being about an inch in breadth opposite the anus. It consists of two strata, superficial and deep. The *superficial*, constituting the main portion of the muscle, *arises* from a narrow tendinous band, the *anococcygeal raphe*, which stretches from the tip of the coccyx to the posterior margin of the anus; it forms two flattened planes of muscle tissue, which encircle the anus and meet in front of be *inserted* into the central tendinous point of the perineum, joining with the Transversus perinei, the Levator ani, and the Accelerator urinae. The *deeper portion* forms a complete sphincter to the anal canal. Its fibres surround the canal, closely applied to the Internal sphincter, and in front blend with the other muscles at the central point of the perineum. In a considerable proportion of cases the fibres decussate in front of the anus, and are continuous with the Transversus perinei. Posteriorly, they are not attached to the coccyx, the fibres of opposite sides being continuous behind the anal canal. The upper edge of the muscle is ill-defined, since fibres are given off from it to join the Levator ani.

Nerve-supply.—A branch from the fourth sacral and twigs from the inferior hemorrhoidal branch of the internal pudic supply the muscle.

Actions.—The action of this muscle is peculiar: (1) It is, like other muscles, always in a state of tonic contraction, and having no antagonistic muscle it keeps the anal canal and orifice closed. (2) It can be put into a condition of greater contraction under the influence of the will, so as more firmly to occlude the anal aperture in expiratory efforts, unconnected with defecation. (3) Taking its fixed point at the coccyx, it helps to fix the central point of the perineum, so that the Accelerator urinae may act from this fixed point.

The **Internal sphincter ani** (*m. sphincter ani internus*) is a ring of muscle which surrounds the anal canal for about an inch; its inferior border being contiguous with, but quite separate from, the External sphincter. This muscle is about a sixth of an inch in thickness, and is formed by an aggregation of the involuntary circular fibres of the intestine. It surrounds the canal for about an

inch, its lower border being about a quarter of an inch from the external orifice. It is paler in color and less coarse in texture than the External sphincter.

Actions.—Its action is entirely involuntary. It helps the External sphincter to occlude the anal aperture.

The **Ischiorectal fossa** (*fossa ischiorectalis*) (Figs. 334 and 344) is situated between the end of the rectum and the ischial tuberosity. It is triangular in shape; its **base**, directed to the surface of the body, is formed by the integument of the ischiorectal region; its **apex**, directed upward, corresponds to the point of division of the obturator fascia and the thin membrane given off from it, which covers the outer surface of the Levator ani (ischiorectal or anal fascia). Its dimensions are about an inch in breadth at the base and about two inches in depth, being deeper behind than in front. It is bounded, *internally*, by the Sphincter ani, Levator ani, and the Coccygeus muscles; *externally*, by the tuberosity of the ischium and the obturator fascia, which covers the inner surface of the Obturator internus muscle; in *front*, it is limited by the line of junction of the superficial fascia with the base of the triangular ligament; and *behind*, by the margin of the Gluteus maximus muscle and the great sacrosciatic ligament. This space is filled with a large mass of adipose tissue, which explains the frequency with which abscesses in the neighborhood of the rectum burrow to a considerable depth.

The fascia covering the inferior surface of the pelvic diaphragm is known as the **anal fascia** (*fascia inferior diaphragmatis pelvis*). It is attached above to the obturator fascia along the line of origin of the Levator ani, while below it is continuous with the deep layer of the triangular ligament and with the fascia on the Internal sphincter ani. The layer covering the upper surface of the pelvic diaphragm (*pars diaphragmatica fasciæ pelvis*) follows, *above*, the line of origin of the Levator ani, and is therefore somewhat variable. In *front* it is attached to the back of the symphysis pubis about three-quarters of an inch above its lower border. It can then be traced outward across the back of the body of the pubis for a distance of about half an inch, where it joins the obturator fascia. It is attached to this fascia along a line which pursues a somewhat irregular course to the spine of the ischium. The irregularity of this line is due to the fact that the origin of the Levator ani, which in lower forms is from the pelvic brim, is in man lower down, on the obturator fascia. Tendinous fibres of origin of the muscle are therefore often found extending up toward, and in some cases reaching, the pelvic brim, and on these the fascia is carried.

MUSCLES AND FASCIÆ OF THE UPPER EXTREMITY.

The muscles of the upper extremity are divisible into groups, corresponding with the different regions of the limb.

I. OF THE THORACIC REGION.

1. Anterior Thoracic Region.

Pectoralis major. Pectoralis minor.
Subclavius.

Interossei palmares.
Interossei dorsales.

Dissection of Pectoral Region and Axilla (Fig. 346).—The arm being drawn away from the side nearly at right angles with the trunk and rotated outward, make a vertical incision through the integument in the median line of the thorax, from the upper to the lower part of the sternum; a second incision along the lower border of the Pectoral muscle, from the ensiform cartilage to the inner side of the axilla; a third, from the sternum along the clavicle, as far as its centre; and a fourth, from the middle of the clavicle obliquely downward, along the interspace between the Pectoral and Deltoid muscles, as low as the fold of the axilla. The flap of integument is then to be dissected off in the direction indicated in the figure, but not entirely removed, as it should be replaced on completing the dissection. If a transverse incision is now made from the lower end of the sternum to the side of the thorax, as far as the posterior fold of the axilla, and the integument reflected outward, the axillary space will be more completely exposed.

I. THE MUSCLES AND FASCIÆ OF THE THORACIC REGION.

1. *The Anterior Thoracic Region.*

Pectoralis major.
[Sternalis.]

Pectoralis minor.
Subclavius.

The **superficial fascia** of the thoracic region is a loose cellulofibrous layer enclosing masses of fat in its spaces. It is continuous with the superficial fascia of the neck and upper extremity above, and with that of the abdomen below. Oppo-

site the mamma it divides into two layers, one of which passes in front, the other behind that gland; and from both of these layers numerous septa pass into its substance, supporting its various lobes; from the anterior layer fibrous processes pass forward to the integument and nipple. These processes were called by Sir A. Cooper the **suspensory ligaments** (*ligamenta suspensoria*), from the support they afford to the gland in this situation.

The **deep thoracic fascia** is a thin aponeurotic lamina, covering the surface of the great Pectoral muscle, and sending numerous prolongations between its fasciculi; it is attached, in the mid-line, to the front of the sternum, and above to the clavicle; externally and below it becomes continuous with the fascia over the shoulder, axilla, and thorax. It is very thin over the upper part of the muscle, thicker in the interval between the Pectoralis major and Latissimus dorsi, where it closes in the axillary space, and is known as the **axillary fascia** (*fascia axillaris*). It passes behind into the fascia of the Latissimus dorsi and Teres major, in front into the fascia of the Deltoid and outward into the fascia of the arm. The fascia of the Latissimus dorsi divides at the outer margin of the muscle into two layers, one of which passes in front and the other behind it; these proceed as far as the spinous processes of the thoracic vertebræ, to which they are attached. As the axillary fascia leaves the lower edge of the Pectoralis major to pass across the floor of the axilla it sends a layer upward under cover to the muscle, the **deep pectoral fascia**; this lamina splits to envelop the Pectoralis minor, at the upper edge of which it becomes continuous with the **costocoracoid membrane** (*clavipectoral fascia*). The hollow of the axilla, seen when the arm is abducted, is mainly produced by the traction of this fascia on the axillary floor, the **axillary fascia**, hence it is sometimes named the **suspensory ligament of the axilla**. The axillary fascia is not a distinct and complete rigid floor of the axillary space. Like all other fasciæ, it follows muscular planes, and splits to encompass vessels, nerves, and muscles. In it are numerous perforations. At the lower part of the thoracic region the deep thoracic fascia is well developed, and is continuous with the fibrous sheath of the Recti abdominis.

The **Pectoralis major** (*m. pectoralis major*) (Fig. 347) is a broad, thick, triangular muscle, situated at the upper and fore part of the thorax, in front of the axilla. It *arises* from the anterior surface of the sternal half of the clavicle; from half the breadth of the anterior surface of the sternum, as low down as the attachment of the cartilage of the sixth or seventh rib; this portion of its origin consists of aponeurotic fibres, which intersect with those of the opposite muscle; it also *arises* from the cartilages of all true ribs, with the exception, frequently, of the first

FIG. 346.—Dissection of the upper extremity.

or the seventh, or both; and from the aponeurosis of the External oblique muscle of the abdomen. The fibres from this extensive origin converge toward its insertion, giving to the muscle a radiated appearance. Those fibres which arise from the clavicle pass obliquely outward and downward and are usually separated from the rest by a cellular interval; those from the lower part of the sternum, and the cartilages of the lower true ribs, pass upward and outward, while the middle fibres pass horizontally. They all terminate in a flat tendon, about two inches

FIG. 347.—Muscles of the thorax and front of the arm. Superficial view.

broad, which is *inserted* into the outer bicipital ridge of the humerus. This tendon consists of two laminæ, placed one in front of the other, and usually blended together below. The *superficial*, the thicker, receives the clavicular and upper half of the sternal portion of the muscle; and its fibres are inserted in the same order as that in which they arise; that is to say, the outermost fibres of origin from the clavicle are inserted at the uppermost part of the tendon; the upper fibres

of origin from the sternum pass down to the lowermost part of this superficial lamina of the tendon and extend as low as the tendon of the Deltoid and join with it. The *deep lamina* of the tendon receives the attachment of the lower half of the sternal portion and the deeper part of the muscle from the costal cartilages. These deep fibres, and particularly those from the lower costal cartilages ascend, the higher turning backward successively behind the superficial and upper ones, so that the tendon appears to be twisted. The deep lamina reaches higher on the humerus than the superficial one, and from it an expansion is given off which covers the bicipital groove and blends with the capsule of the shoulder-joint. From the deepest fibres of this lamina at its insertion an expansion is given off which lines the bicipital groove of the humerus, while from the lower border of the tendon a third expansion passes downward to the fascia of the arm. Between the posterior surface of the tendon of the Great pectoral and the anterior surface of the long head of the Biceps there is usually a bursa (*bursa m. pectoralis majoris*).

FIG. 348.—Costocoracoid membrane.

Relations.—By its *superficial surface*, with the integument, the superficial fascia, the Platysma, some of the branches of the descending cervical nerves, the mammary gland, and the deep fascia; by its *deep surface*: its *thoracic portion*, with the sternum, the ribs and costal cartilages, the costocoracoid membrane, the Subclavius, Pectoralis minor, Serratus magnus, and the Intercostals; its *axillary portion* forms the anterior wall of the axillary space, and covers the axillary vessels and nerves, the Biceps brachii and Coracobrachialis muscles. Its *upper border* lies parallel with the Deltoid, from which it is separated by a slight interspace in which lie the cephalic vein and humeral branch of the acromial thoracic artery. Its *lower border* forms the anterior margin of the axilla, being at first separated from the Latissimus dorsi by a considerable interval; but both muscles gradually converge toward the outer part of the space.

A **Sternalis** muscle is occasionally found in the pectoral region; it may be confined to one side, or may be bilateral. It is sometimes represented by delicate scattered fibres overlying a normal Pectoralis major, or by a well-developed muscle associated with a defective Pectoralis major. It is often attached to the sternal end of the Sternomastoid; below, it becomes lost in the presternal fascia or in the aponeurosis of the External oblique. This variant is regarded as a displaced and rotated segment of the Pectoralis major; it is supplied by branches from the anterior thoracic nerve.

Dissection.—Detach the Pectoralis major by dividing the muscle along its attachment to the clavicle, and by making a vertical incision through its substance a little external to its line of attachment to the sternum and costal cartilages. The muscle should then be reflected outward, and its tendon carefully examined. The Pectoralis minor is now exposed, and immediately above it, in the interval between its upper border and the clavicle, a strong fascia, the costo-coracoid membrane.

FIG. 349.—Muscles of the thorax and front of the arm, showing some of the boundaries of the axilla.

The **Costocoracoid Membrane**, or the **Clavipectoral Fascia** (*fascia coraco-clavicularis*), is a strong fascia, situated under cover of the clavicular portion of the Pectoralis major muscle. It occupies the interval between the Pectoralis minor and Subclavius muscle, and protects the axillary vessels and nerves. Traced upward, it splits to enclose the Subclavius muscle, and its two layers are attached to the clavicle, one in front of and the other behind the muscle; the deep layer fuses with the deep cervical fascia and with the sheath of the axillary vessels. *Mesally*, it blends with the fascia covering the first two intercostal spaces, and is attached also to the first rib internal to the origin of the Subclavius muscle. *Laterally*, it is very thick and dense, and is attached to the coracoid process. The portion

extending from its attachment to the first rib to the coracoid process is often whiter and denser than the rest; this is sometimes called the **costocoracoid ligament**. *Below*, it is thin, and at the upper border of the Pectoralis minor it splits into two layers to invest this muscle; from the lower border of the Pectoralis minor it is continued downward to join the axillary fascia, and outward to join the fascia over the short head of the Biceps. The costocoracoid membrane is pierced by the cephalic vein, the acromiothoracic artery and vein, superior thoracic artery, and anterior thoracic nerve.

The **Pectoralis minor** (*m. pectoralis minor*) (Fig. 349) is a thin, flat, triangular muscle, situated at the upper part of the thorax, beneath the Pectoralis major. It *arises* by three tendinous digitations from the upper margin and outer surface of the third, fourth, and fifth ribs, near their cartilages, and from the aponeurosis covering the Intercostal muscles; the fibres pass upward and outward, and converge to form a flat tendon, which is *inserted* into the inner border and upper surface of the coracoid process of the scapula.

Relations.—By its *superficial surface*, with the Pectoralis major and the thoracic branches of the acromiothoracic artery. By its *deep surface*, with the ribs, Intercostal muscles, Serratus magnus, the axillary space, and the axillary vessels and brachial plexus of nerves. Its upper border is separated from the clavicle by a narrow triangular interval, occupied by the costocoracoid membrane, behind which are the axillary vessels and nerves. The long thoracic artery runs parallel to the lower border of this muscle and the anterior thoracic nerve pierces it.

The costocoracoid membrane should now be removed, and the Subclavius muscle will be exposed.

The **Subclavius** (*m. subclavius*) is a small triangular muscle, placed in the interval between the clavicle and the first rib. It *arises* in front of the rhomboid ligament by a short, thick tendon from the first rib and its cartilage at their junction; the fleshy fibres proceed obliquely upward and outward, to be *inserted* into the groove on the under surface of the clavicle. An extension from the aponeurosis of this muscle lies upon the subclavian vein.

Relations.—Its *deep surface* is separated from the first rib by the subclavian vessels and brachial plexus of nerves. Its *superficial surface* is separated from the Pectoralis major by the costocoracoid membrane, which, with the clavicle, forms an osseofibrous sheath in which the muscle is enclosed.

If the costal attachment of the Pectoralis minor be divided across, and the muscle reflected outward, the axillary vessels and nerves are brought fully into view, and should be examined.

Nerves.—The Pectoral muscles are supplied by the external and internal anterior thoracic nerves; the Pectoralis major through these nerves receives filaments from all the spinal nerves entering into the formation of the brachial plexus; the Pectoralis minor receives its fibres from the eighth cervical and first thoracic nerves through the internal anterior thoracic nerve. The Subclavius is supplied by a filament derived from the fifth and sixth cervical nerves.

Actions.—If the arm has been raised by the Deltoid, the Pectoralis major will, conjointly with the Latissimus dorsi and Teres major, depress it to the side of the thorax. If acting alone, it adducts and draws forward the arm, bringing it across the front of the thorax, and at the same time rotating it inward. The Pectoralis minor depresses the point of the shoulder, drawing the scapula downward and inward to the thorax, and throwing the inferior angle backward. The Subclavius depresses the shoulder, drawing the clavicle downward and forward. When the arms are fixed, all three muscles act upon the ribs, drawing them upward and expanding the thorax, and thus becoming very important agents in forced inspiration. During an attack of asthma patients always assume an attitude which fixes the shoulders, so that all these muscles may be brought into action to assist in increasing the capacity of the thorax.

2. The Lateral Thoracic Region.

Serratus magnus.

The **Serratus magnus** (*m. serratus anterior*) (Fig. 349) is a thin, irregularly quadrilateral muscle, situated between the ribs and the scapula at the upper and lateral part of the thorax. It *arises* by fleshy digitations or slips from the outer surfaces and upper borders of the upper eight or nine ribs, and from the aponeuroses covering the intervening intercostal muscles. Each digitation (except the first) *arises* from the corresponding rib; the first digitation arises from the first and second ribs and from the fascia covering the first intercostal space. From this extensive attachment the fibres pass backward, closely applied to the thoracic wall, and reach the vertebral border of the scapula, and are inserted into its ventral aspect in the following manner. The first digitation, arising from the first and second ribs, is *inserted* into a triangular area on the ventral aspect of the superior angle. The next two digitations (from the second and third ribs) spread out to form a thin triangular sheet, the base of which is directed backward and is *inserted* into nearly the whole length of the ventral aspect of the vertebral border. The lower five or six digitations converge to form a fan-shaped mass, the apex of which is *inserted*, by muscular and tendinous fibres, into a triangular impression on the ventral aspect of the inferior angle. The lower four slips interdigitate at their origin with the upper five slips of the External oblique muscle of the abdomen.

Relations.—This muscle is partly covered, in *front*, by the Pectoral muscles; *behind*, by the Subscapularis. The axillary vessels and nerves lie upon its upper part, while its *deep surface* rests upon the ribs and intercostal muscles.

Nerves.—The Serratus magnus is supplied by the posterior thoracic nerve, which is derived from the fifth, sixth, and seventh cervical nerves.

Actions.—The Serratus magnus, as a whole, carries the scapula forward, and at the same time raises the vertebral border of the bone. It is therefore concerned in the action of pushing. Its lower and stronger fibres move forward the lower angle and assist the Trapezius in rotating the bone around an axis through its centre, and thus assist this muscle in raising the acromion and supporting weights upon the shoulder. It also assists the Deltoid in raising the arm, inasmuch as during the action of this latter muscle it fixes the scapula and so steadies the glenoid cavity in which the head of the humerus rotates. After the Deltoid has raised the arm to a right angle with the trunk, the Serratus magnus and the Trapezius, by rotating the scapula, raise the arm into an almost vertical position. It is possible that when the shoulders are fixed the lower fibres of the Serratus magnus may assist in raising and everting the ribs; but it is not the important inspiratory muscle which it was formerly believed to be.

Applied Anatomy.—When the muscle is paralyzed, the vertebral border, and especially the lower angle of the scapula, leaves the ribs and stands out prominently on the surface, giving a peculiar “winged” appearance to the back. The patient is unable to raise the arm, and an attempt to do so is followed by a further projection of the lower angle of the scapula from the back of the thorax.

Dissection.—After completing the dissection of the axilla, if the muscles of the back have been dissected, the upper extremity should be separated from the trunk. Saw through the clavicle at its centre, and then cut through the muscles which connect the scapula and arm with the trunk—viz., the Pectoralis minor in front, Serratus magnus at the side, and the Levator anguli scapulae, the Rhomboids, Trapezius, and Latissimus dorsi behind. These muscles should be cleaned and traced to their respective insertions. Then make an incision through the integument, commencing at the outer third of the clavicle, and extending along the margin of that bone, the acromion process, and spine of the scapula; the integument should be dissected from above downward and outward, when the fascia covering the Deltoid will be exposed (Fig. 346, No. 3).

II. MUSCLES AND FASCIÆ OF THE SHOULDER AND ARM.

The **superficial fascia** of the upper extremity is a thin cellulofibrous layer, containing the superficial veins and lymphatics, and the cutaneous nerves. It is

most distinct in front of the elbow, and contains very large superficial veins and nerves; in the hand it is hardly demonstrable, the integument being closely adherent to the deep fascia by dense fibrous bands. Small subcutaneous bursæ are found in this fascia over the acromion, the olecranon, and the knuckles.

The **deep fascia** of the upper extremity comprises the aponeurosis of the shoulder, arm, and forearm, the anterior and posterior annular ligaments of the carpus, and the palmar fascia. These will be considered in the description of the muscles of the several regions.

3. The Acromial Region.

Deltoid.

The **deep fascia** covering the Deltoid invests this muscle and sends down numerous prolongations between its fasciculi. In *front*, it is continuous with the fascia covering the great Pectoral muscle; *behind*, with that covering the Infraspinatus; *above*, it is attached to the clavicle, the acromion, and spine of the scapula; *below*, it is continuous with the deep fascia of the arm.

The **Deltoid** (*m. deltoideus*) (Fig. 347) is a large, thick, triangular muscle, which gives the rounded outline to the shoulder, and has received its name from its resemblance to the Greek letter Δ (*delta*) inverted. It covers the shoulder-joint in front, behind, and on its outer side. It *arises* from the outer third of the anterior border and upper surface of the clavicle; from the outer margin and upper surface of the acromion process, and from the lower lip of the posterior border of the spine of the scapula, as far back as the triangular surface at its mesal end. From this extensive origin the fibres converge toward their insertion, the middle passing vertically, the anterior obliquely backward, the posterior obliquely forward, they unite to form a thick tendon, which is *inserted* into a rough triangular prominence on the middle of the outer side of the shaft of the humerus. At its insertion the muscle gives off an expansion to the deep fascia of the arm. This muscle is remarkably coarse in texture, and the arrangement of its muscle fibres is somewhat peculiar; the central portion of the muscle—that is to say, the part arising from the acromion process—consists of fibres having an oblique direction, which arise in a bipenniform manner from the sides of tendinous intersections, generally four in number, which are attached above to the acromion process and pass downward parallel to one another in the substance of the muscle. The oblique muscle fibres thus formed are inserted into similar tendinous intersections, generally three in number, which pass upward from the insertion of the muscle into the humerus and alternate with the descending septa. The portions of the muscle which arise from the clavicle and spine of the scapula are not arranged in this manner, but pass from their origin above, to be inserted into the margins of the inferior tendon.

Relations.—By its *superficial surface*, the Deltoid is in relation with the integument, the superficial and deep fasciæ, Platysma, and supra-acromial nerves. Its *deep surface* is separated from the capsule of the shoulder-joint by a large sacculated synovial bursa, the **subdeltoid bursa** (*bursa subdeltoidea*). It often communicates with the **subacromial bursa** (*bursa subacromialis*), which is between the acromial process and the coraco-acromial ligament above and the capsule of the shoulder-joint and the Supraspinatus muscle below. The deep surface of the Deltoid covers the coracoid process, coraco-acromial ligament, Pectoralis minor, Coracobrachialis, both heads of the Biceps, the tendon of the Pectoralis major, the insertions of the Supraspinatus, Infraspinatus, and Teres minor, the scapular and external heads of the Triceps, the circumflex vessels and nerve, and the humerus. Its *anterior border* is separated at its upper part from the Pectoralis major by a cellular interspace, which lodges the cephalic vein and humeral branch of the acromiothoracic artery; lower down the two muscles are in close contact. Its *posterior border* rests on the Infraspinatus and Triceps muscles.

Nerves.—The Deltoid is supplied by the fifth and sixth cervical through the circumflex nerve.

Actions.—The Deltoid raises the arm directly from the side, so as to bring it to a right angle with the trunk, but this act cannot be performed without the aid of the Serratus magnus, which muscle steadies the lower angle of the scapula. Its anterior fibres, assisted by the Pectoralis major, draw the arm forward; and its posterior fibres, aided by the Teres major and Latissimus dorsi, draw it backward.

Applied Anatomy.—The Deltoid is very liable to atrophy, and when in this condition dislocation of the shoulder-joint is simulated, as there is flattening of the shoulder and apparent prominence of the acromion process; upon examination, however, it will be found that the relative position of the greater tuberosity of the humerus to the acromion and coracoid process is unchanged. Atrophy of the Deltoid may be due to disuse or loss of trophic influence, either from injury to the circumflex nerve (as in "*crutch-palsy*") or from spinal cord lesions, as in *infantile paralysis*. In the operation performed for the obliteration of the subdeltoid bursa, the incision through the Deltoid should be as far anterior as possible, in order to avoid severing the nerves which enter the muscle from behind.

4. The Anterior Scapular Region.

Subscapularis.

Dissection.—Divide the Deltoid across, near its upper part, by an incision carried along the margin of the clavicle, the acromion process and spine of the scapula, and reflect it downward, when the structures under cover of it will be seen.

FIG. 350.—Diagram showing attachment of muscles of the shoulder and arm. Anterior aspect. Origins, red; insertions, blue.

The **subscapular fascia** (*fascia subscapularis*) is a thin membrane attached to the entire circumference of the subscapular fossa, and affording attachment by its inner surface to some of the fibres of the Subscapularis muscle.

The **Subscapularis** (*m. subscapularis*) (Fig. 349) is a large triangular muscle which fills up the subscapular fossa, *arising* from its internal two-thirds, with the exception of a narrow margin along the internal border, and the surfaces at the superior and inferior angles which afford attachment to the Serratus magnus; it also arises from the lower two-thirds of the groove on the axillary border of the bone. Some fibres arise from the tendinous laminae, which intersect the muscle, and are attached to ridges on the bone; and others from an aponeurosis, which separates the muscles from the Teres major and the long head of the Triceps. The fibres pass outward, and, gradually converging, terminate in a tendon, which is *inserted* into the lesser tuberosity of the humerus and into the neck of the humerus just behind this tuberosity and in front of the capsular ligament of the shoulder-joint. The tendon of the muscle is in close contact with the anterior part of the capsular ligament of the shoulder-joint, and glides over a large bursa (*bursa m. subscapularis*), which separates it from the base of the coracoid process. This bursa communicates with the cavity of the joint by an aperture in the capsular ligament.

Relations.—Its *deep surface* forms a considerable part of the posterior wall of the axilla, and is in relation with the Serratus magnus, Coracobrachialis, and Biceps, the axillary vessels and brachial plexus of nerves, and the subscapular vessels and nerves. By its *superficial surface*, with the scapula and the capsular ligament of the shoulder-joint. Its *lower border* is contiguous to the Teres major and Latissimus dorsi.

Nerves.—It is supplied by the fifth and sixth cervical nerves through the upper and lower subscapular nerves.

Actions.—The Subscapularis rotates the head of the humerus inward; when the arm is raised, it draws the humerus forward and downward. It is a powerful defence to the front of the shoulder-joint, preventing displacement of the head of the bone.

5. The Posterior Scapular Region (Figs. 351, 352).

Supraspinatus.
Infraspinatus.

Teres minor.
Teres major.

Dissection.—To expose these muscles, and to examine their insertion into the humerus, detach the Deltoid and Trapezius from their attachment to the spine of the scapula and acromion process. Remove the clavicle by dividing the ligaments connecting it with the coracoid process, and separate it at its articulation with the scapula; divide the acromion process near its root with a saw. The fragments being removed, the tendons of the posterior Scapular muscles will be fully exposed. A block should be placed beneath the shoulder-joint, so as to make the muscles tense.

The **supraspinatus fascia** (*fascia supraspinata*) is a thick and dense membranous layer, which completes the osseofibrous case in which the Supraspinatus muscle is contained; it affords attachment, by its deep surface, to some of the fibres of the muscle. It is thick internally, but thinner externally under the coraco-acromial ligament.

The **Supraspinatus muscle** (*m. supraspinatus*) occupies the whole of the supraspinous fossa, *arising* from its internal two-thirds and from the strong fascia which covers the surface of the muscle. The muscle fibres converge to a tendon which passes across the upper part of the capsular ligament of the shoulder-joint, to which it is intimately adherent, and is *inserted* into the highest of the three facets on the greater tuberosity of the humerus.

Relations.—By its *superficial surface*, with the Trapezius, the clavicle, the acromion, the coraco-acromial ligament, and the Deltoid; by its *deep surface*, with the scapula, the suprascapular vessels and nerve, and upper part of the shoulder-joint.

The **infraspinatus fascia** (*fascia infraspinata*) is a dense fibrous membrane, covering in the Infraspinatus muscle and attached to the circumference of the

infraspinous fossa; it affords attachment, by its inner surface, to some fibres of that muscle. At the point where the Infraspinatus commences to be covered by the Deltoid, this fascia divides into two layers; one layer passes over the Deltoid muscle, helping to form the deltoid fascia already described; the other passes beneath the Deltoid to the capsule of the shoulder-joint.

FIG. 351.—Diagram showing attachment of muscles of shoulder and arm. Posterior aspect. Origins, red; insertions, blue.

The **Infraspinatus** (*m. infraspinatus*) is a thick, triangular muscle, which occupies the chief part of the infraspinous fossa, *arising* by fleshy fibres from its internal two-thirds, and by tendinous fibres from the ridges on its surfaces; it also arises from a strong fascia which covers it externally, and separates it from the Teres major and minor. The fibres converge to a tendon which glides over the external border of the spine of the scapula, and, passing across the posterior part of the capsular ligament of the shoulder-joint, is *inserted* into the middle impression on the greater tuberosity of the humerus. The tendon of this muscle is sometimes separated from the capsule of the shoulder-joint by a synovial bursa (*bursa m. infraspinati*), which may communicate with the joint-cavity.

Relations.—By its *superficial surface*, with the Deltoid, the Trapezius, Latissimus dorsi, and the integument; by its *deep surface*, with the scapula, from which it is separated by the supra-scapular and dorsalis scapulae vessels, and with the capsular ligament of the shoulder-joint. Its *lower border* is in contact with the Teres minor, occasionally united with it, and with the Teres major.

The **Teres minor** (*m. teres minor*) is a narrow, elongated muscle, which *arises* from the dorsal surface of the axillary border of the scapula for the upper two-thirds of its extent, and from the two aponeurotic laminae, one of which separates this muscle from the *Infraspinatus*, the other from the *Teres major*; its fibres pass obliquely upward and outward, and terminate in a tendon which is *inserted* into the lowest of the three facets on the greater tuberosity of the humerus, and by fleshy fibres, into the humerus immediately below it. The tendon of this muscle passes across the posterior part of the capsular ligament of the shoulder-joint.

Relations.—By its *superficial surface*, with the Deltoid and the integument; by its *deep surface*, with the scapula and dorsal branch of the subscapular artery, the long head of the *Triceps*, and the shoulder-joint; by its *upper border*, with the *Infraspinatus*; by its *lower border*, with the *Teres major*, from which it is separated anteriorly by the long head of the *Triceps*.

FIG. 352.—Muscles on the dorsum of the Scapula and the Triceps.

The **Teres major** (*m. teres major*) is a thick but somewhat flattened muscle, which *arises* from the oval surface on the dorsal aspect of the inferior angle of the scapula, and from the fibrous septa interposed between it and the *Teres minor* and *Infraspinatus*; the fibres are directed upward and outward, and terminate in a flat tendon, about two inches in length, which is *inserted* into the inner bicipital ridge of the humerus. The tendon of this muscle, at its insertion into the humerus, lies behind that of the *Latissimus dorsi*, from which it is separated by a synovial bursa, the two tendons being, however, united along their lower borders for a short distance. A bursa (*bursa m. teretis majoris*) is found between the tendon of the *Teres major* and the bone.

Relations.—By its *superficial surface*, with the Latissimus dorsi below, and the long head of the Triceps above. By its *deep surface*, with the Subscapularis, Latissimus dorsi, Coracobrachialis, short head of the Biceps brachii, the axillary vessels, and brachial plexus of nerves. Its *upper border* is at first in relation with the Teres minor, from which it is afterward separated by the long head of the Triceps. Its *lower border* forms, in conjunction with the Latissimus dorsi, part of the posterior boundary of the axilla. The Latissimus dorsi at first covers the origin of the Teres major, then wraps itself obliquely around its lower border, so that its tendon ultimately comes to lie in front of that of the Teres major.

Nerves.—The Supra- and Infraspinatus muscles are supplied by the fifth and sixth cervical nerves through the suprascapular nerve; the Teres minor, by the fifth cervical, through the circumflex; and the Teres major, by the fifth and sixth cervical, through the lower subscapular.

Actions.—The Supraspinatus assists the Deltoid in raising the arm from the side, and fixes the head of the humerus in the glenoid cavity. The Infraspinatus and Teres minor rotate the head of the humerus outward; when the arm is raised, they assist in retaining it in that position and carrying it backward. One of the most important uses of these three muscles is the great protection they afford to the shoulder-joint, the Supraspinatus supporting it above, and preventing displacement of the head of the humerus upward, while the Infraspinatus and Teres minor protect it behind, and prevent dislocation backward. The Teres major assists the Latissimus dorsi in drawing the humerus downward and backward, when previously raised, and in rotating it inward; when the arm is fixed, it may assist the Pectoral and Latissimus dorsi muscles in drawing the trunk forward.

THE MUSCLES AND FASCIÆ OF THE ARM.

6. The Anterior Humeral Region (Fig. 349).

Coracobrachialis.

Biceps.

Brachialis anticus.

Dissection.—The arm being placed on the table, with the front surface uppermost, make a vertical incision through the integument along the middle line, from the clavicle to about two inches below the elbow-joint, where it should be joined by a transverse incision, extending from the inner to the outer side of the forearm; the two flaps being reflected on either side, the fascia should be examined (Fig. 346).

The *deep fascia (fascia brachii)* of the arm is continuous with that covering the Deltoid and the great Pectoral muscles, by means of which it is attached, above, to the clavicle, acromion, and spine of the scapula, and it is also continuous with the axillary fascia. It forms a thin, loose, membranous sheath investing the muscles of the arm, sending down septa between them, and is composed of fibres disposed in a circular or spiral direction, and connected by vertical and oblique fibres. It differs in thickness at different parts, being thin over the Biceps brachii, but thicker where it covers the Triceps, and over the condyles of the humerus; it is strengthened by fibrous aponeuroses, derived from the Pectoralis major and Latissimus dorsi, on the inner side, and from the Deltoid externally. On either side it gives off a strong *intermuscular septum*, which is attached to the supracondylar ridge and to the condyle of the humerus. These septa serve to separate the muscles of the anterior from those of the posterior brachial region. The *external intermuscular septum* extends from the lower part of the external bicipital ridge, along the external supracondylar ridge, to the outer condyle; it is blended with the tendon of the Deltoid, gives attachment to the Triceps behind, to the Brachialis anticus, Brachioradialis, and Extensor carpi radialis longior in front. It is perforated by the musculospiral nerve and the anterior terminal branch of the superior profunda artery. The *internal intermuscular septum*, thicker than the preceding, extends from the lower part of the internal lip of the bicipital groove below the Teres major, along the internal supracondylar ridge to the inner condyle; it is blended with the tendon of the Coracobrachialis, and affords attachment to the Triceps behind, and the Brachialis anticus in front. It is perforated by the ulnar nerve and the inferior profunda and anastomotica magna arteries. At

the elbow the deep fascia is attached to all the prominent points around the joint—viz., the condyles of the humerus and the olecranon process of the ulna—and is continuous with the deep fascia of the forearm. Just below the middle of the arm, on its inner side, in front of the intermuscular septum, is an oval opening in the deep fascia which transmits the basilic vein and some lymphatic vessels.

FIG. 353.—Horizontal section at middle of right arm—upper surface of lower segment. B. V., basilic vein. CEPH. V., cephalic vein. I. C. N., internal cutaneous nerve. I. P. A., inferior profunda artery. M. C. N., musculocutaneous nerve. M. N., median nerve. M. S. N., musculospiral nerve. S. P. A., superior profunda artery. U. N., ulnar nerve. (After Braune.)

The **Coracobrachialis** (*m. coracobrachialis*), the smallest of the three muscles in this region, is situated at the upper and inner part of the arm. It arises by fleshy fibres from the apex of the coracoid process, in common with the short head of the Biceps, and from the intermuscular septum between the two muscles; the fibres pass downward, backward, and a little outward, to be inserted by means of a flat tendon into an impression at the middle of the inner surface and internal border of the shaft of the humerus between the crigins of the Triceps and Brachialis anticus. It is perforated by the musculocutaneous nerve. The inner border of the muscle forms a guide to the position of the terminal portion of the axillary and upper part of the brachial arteries.

Relations.—By its *superficial surface*, with the Pectoralis major above, and at its insertion with the brachial vessels and median nerve which cross it; by its *deep surface*, with the tendons of the Subscapularis, Latissimus dorsi, and Teres major, the inner head of the Triceps, the

humerus, and the anterior circumflex vessels; by its *inner border*, with the brachial artery, and the median and musculocutaneous nerves; by its *outer border*, with the short head of the Biceps and Brachialis anticus.

The **Biceps**, or the **Biceps flexor cubiti** (*m. biceps brachii*), is a long fusiform muscle, occupying the whole of the anterior surface of the arm, and divided above into two portions or heads, from which circumstance it has received its name. The **short head** (*caput breve*) arises by a thick flattened tendon from the apex of the coracoid process, in common with the Coracobrachialis. The **long head** (*caput longum*) arises from the upper margin of the glenoid cavity, and is continuous with the glenoid ligament. This tendon arches over the head of the humerus, being enclosed in a special sheath of the synovial membrane of the shoulder-joint; it then passes through an opening in the capsular ligament at its attachment to the humerus, and descends in the bicipital groove, in which it is retained by a fibrous prolongation from the tendon of the Pectoralis major. Each tendon is succeeded by an elongated muscle belly, and the two bellies, although closely applied to each other, can readily be separated until within about three inches of the elbow-joint. Here they end in a flattened tendon, which is *inserted* into the back part of the tuberosity of the radius, a synovial bursa, being interposed between the tendon and the front of the tuberosity; another bursa is often interposed between the ulna and the tendon. As the tendon of the muscle approaches the radius it becomes twisted upon itself, so that its anterior surface becomes external and is applied to the tuberosity of the radius at its insertion; opposite the bend of the elbow the tendon gives off, from its inner side, a broad aponeurosis, the **bicipital fascia** (*lacertus fibrosus*), which passes obliquely downward and inward across the brachial artery, and is continuous with the deep fascia covering the origins of the superficial Flexor muscles of the forearm (Fig. 342).¹

Relations.—Its *superficial surface* is overlapped above by the Pectoralis major and Deltoid; in the rest of its extent it is covered by the superficial and deep fasciæ and the integument. Its *deep surface* rests above on the shoulder-joint and upper part of the humerus; below it rests on the Brachialis anticus, with the musculocutaneous nerve intervening between the two, and on the Supinator [brevis]. Its *inner border* is in relation with the Coracobrachialis, and overlaps the brachial vessels and median nerve; its *outer border*, with the Deltoid and Brachioradialis.

The **Brachialis anticus** (*m. brachialis*) is a broad muscle, which covers the elbow-joint and the lower half of the front of the humerus. It is somewhat compressed from before backward, and is broader in the middle than at either extremity. It arises from the lower half of the outer and inner surfaces of the shaft of the humerus, and commences above at the insertion of the Deltoid, which it embraces by two angular processes. Its origin extends below, to within an inch of the margin of the articular surface, and is limited on each side by the external and internal borders of the shaft of the humerus. It also arises from the intermuscular septa on each side, but more extensively from the inner, from which it is separated below by the Brachioradialis and Extensor carpi radialis longior. Its fibres converge to a thick tendon, which is *inserted* into a rough depression on the anterior surface of the coronoid process of the ulna, being received into an interval between two fleshy slips of the Flexor profundus digitorum.

Relations.—By its *superficial surface*, with the Biceps, the brachial vessels, musculocutaneous and median nerves; by its *deep surface*, with the humerus and front of the elbow-joint; by its *inner border*, with the Triceps, ulnar nerve, and Pronator teres, from which it is separated by the intermuscular septum; by its *outer border*, with the musculospiral nerve, radial recurrent artery, the Brachioradialis, and Extensor carpi radialis longior.

¹ A third head to the Biceps is occasionally found (Theile says as often as once in eight or nine subjects), arising at the upper and inner part of the Brachialis anticus, with the fibres of which it is continuous, and inserted into the bicipital fascia and inner side of the tendon of the Biceps. In most cases this additional slip passes behind the brachial artery in its course down the arm. Occasionally the third head consists of two slips which pass down, one in front of, the other behind, the artery, concealing the vessel in the lower half of the arm.

Nerves.—The muscles of this group are supplied by the musculocutaneous nerve. The Brachialis anticus usually receives an additional filament from the musculospiral. The Coracobrachialis receives its supply primarily from the seventh cervical, the Biceps and Brachialis anticus from the fifth and sixth cervical nerves.

Actions.—The Coracobrachialis draws the humerus forward and inward, and at the same time assists in elevating it toward the scapula. The Biceps is a flexor of the forearm; it is also a powerful supinator, and serves to render tense the deep fascia of the forearm by means of the broad aponeurosis given off from its tendon. The Brachialis anticus is a flexor of the forearm, and forms an important defence to the elbow-joint. When the forearm is flexed, the Biceps and Brachialis anticus flex the arm upon the forearm, as is seen in efforts at climbing.

7. The Posterior Humeral Region.

Triceps.

Subanconeus.

The **Triceps**, or the **Triceps extensor cubiti** (*m. triceps brachii*) (Fig. 352), is situated on the back of the arm, extending the entire length of the posterior surface of the humerus. It is of large size, and is divided above into three parts; hence its name. These three portions have been named: (1) the middle, scapular, or long head; (2) the external or long humeral head; and (3) the internal or short humeral head.

The **middle or scapular head** (*caput longum*) arises by a flattened tendon from a rough triangular depression on the scapula, immediately below the glenoid cavity, being blended at its upper part with the capsular ligament; the muscle fibres pass downward between the two other portions of the muscle, and join with them in the common tendon of insertion.

The **external head** (*caput laterale*) arises from the posterior surface of the shaft of the humerus, between the insertion of the Teres minor and the upper part of the musculospiral groove; from the external border of the humerus and the external intermuscular septum; the fibres from this origin converge toward the common tendon of insertion.

The **internal head** (*caput mediale*) arises from the posterior surface of the shaft of the humerus, below the groove for the musculospiral nerve; commencing above, narrow and pointed, below the insertion of the Teres major, and extending to within an inch of the trochlear surface; it also arises from the internal border of the humerus, and from the back of the whole length of the internal and lower part of the external intermuscular septum. Certain fibres of this portion of the muscle are directed downward to the olecranon, while others converge to the tendon of insertion.

The **tendon of the triceps** commences about the middle of the back part of the muscle; it consists of two aponeurotic laminæ, one of which is subcutaneous and covers the posterior surface of the muscle for the lower half of its extent; the other is more deeply seated in the substance of the muscle; after receiving the attachment of the muscle fibres, they join above the elbow, and are inserted, for the most part, into the back part of the upper surface of the olecranon process; a band of fibres is, however, continued downward, on the outer side, over the Anconeus, to blend with the deep fascia of the forearm.

Relations.—By its *superficial surface*, the Triceps is in relation with the Deltoid above; in the rest of its extent it is subcutaneous; by its *deep surface*, with the humerus, musculospiral nerve, superior profunda vessels, and back part of the elbow-joint. Its *middle or long head* is in relation, behind, with the Deltoid and Teres minor; in front, with the Subscapularis, Latissimus dorsi, and Teres major.

The long head of the Triceps descends between the Teres minor and Teres major, dividing the triangular space between these two muscles and the humerus into two smaller spaces, one triangular, the other quadrangular (Fig. 352). The **triangular space** contains the dorsalis

scapulae vessels; it is bounded by the Teres minor above, the Teres major below, and the scapular head of the Triceps externally; the **quadrangular space** transmits the posterior circumflex vessels and the circumflex nerve; it is bounded by the Teres minor above, the Teres major below, the scapular head of the Triceps internally, and the humerus externally.

The **Subanconeus** is a name given to a few fibres from the under surface of the lower part of the Triceps muscle, which are *inserted* into the posterior ligament of the elbow-joint. By some authors it is regarded as the homotype of the Subcrureus in the lower limb, but it is not a separate muscle.

Nerves.—The Triceps is supplied by the seventh and eighth cervical nerves through the musculospiral nerve.

Actions.—The Triceps is the great Extensor muscle of the forearm, serving, when the forearm is flexed, to extend the elbow-joint. It is the direct antagonist of the Biceps and Brachialis anticus. When the arm is extended the long head of the muscles may assist the Teres major and Latissimus dorsi in drawing the humerus backward and in adducting it to the thorax. The long head of the Triceps protects the under part of the shoulder-joint, and prevents displacement of the head of the humerus downward and backward. The Subanconeus draws up the synovial membrane of the elbow-joint out of the way of the advancing olecranon process during extension of the forearm.

Applied Anatomy.—The existence of the band of fibres from the Triceps to the fascia of the forearm is of importance in excision of the elbow, and should always be carefully preserved from injury by the operator, as by means of these fibres the patient is enabled to extend the forearm, a movement which would otherwise mainly be accomplished by gravity—that is to say, allowing the forearm to drop from its own weight.

III. MUSCLES AND FASCIÆ OF THE FOREARM.

Dissection.—To dissect the forearm, place the limb in the position indicated in Fig. 346, make a vertical incision along the middle line from the elbow to the wrist, and a transverse incision at the extremity of this; the superficial structures being removed, the deep fascia of the forearm is exposed.

The **deep fascia** of the forearm (*fascia antibrachii*),¹ continuous above with that enclosing the arm, is a dense, highly glistening aponeurotic investment, which forms a general sheath enclosing the muscles in this region; it is attached, *behind*, to the olecranon and posterior border of the ulna, and gives off from its inner surface numerous *intermuscular septa*, which enclose each muscle separately. *Below*, it is continuous in front with the *anterior annular ligament*, and forms a sheath for the tendon of the Palmaris longus muscle, which passes over the annular ligament to be inserted into the palmar fascia. *Behind*, near the wrist-joint, it becomes much thickened by the addition of many transverse fibres, and forms the posterior annular ligament. It consists of circular and oblique fibres, connected by numerous vertical fibres. It is much thicker on the dorsal than on the palmar surface, and at the lower than at the upper part of the forearm, and is strengthened above by tendinous fibres derived from the Brachialis anticus and Biceps in front, and from the Triceps behind. Its deep surface gives origin to muscle fibres, especially at the upper part of the inner and outer sides of the forearm, and forms the boundaries of a series of conical-shaped cavities, in which the muscles are contained. Besides the vertical septa separating each muscle, transverse septa are given off on the anterior and posterior surfaces of the forearm, separating the deep from the superficial layer of muscles. Numerous apertures exist in the fascia for the passage of vessels and nerves; one of these, of large size, situated at the front of the elbow, serves for the passage of a communicating branch between the superficial and deep veins. This fascia is also perforated on its anterior surface, near the wrist, by the ulnar artery and nerve.

¹ The correct spelling is *antebrachium*, not *antibrachium*, as is given in the list of the BNA.—[EDITOR.]

The muscles of the forearm may be subdivided into groups corresponding to the region they occupy. One group occupies the inner and anterior aspect of the forearm, and comprises the Flexor and Pronator muscles. Another group occupies its outer side, and a third its posterior aspect. The two latter groups include all the Extensor and Supinator muscles.

FIG. 354.—Transverse section through the middle of the right forearm, in the position of semipronation. (After Braune.)

8. The Anterior Radioulnar Region.

The muscles in this region are divided for convenience of description into two groups or layers, **superficial** and **deep**.

The Superficial Layer.

Pronator teres.

Flexor carpi radialis.

Flexor sublimis digitorum.

Palmaris longus.

Flexor carpi ulnaris.

These muscles take partial origin from the internal condyle of the humerus by a common tendon.

The **Pronator teres** (*m. pronator teres*) has two heads. One (*caput humerale*), the larger and more superficial, arises from the humerus, immediately above the internal condyle, from the tendon common to the origin of the other muscles; and from the fascia of the forearm and the intermuscular septum between it and the Flexor carpi radialis. The deep head (*caput ulnare*) is a thin fasciculus

which *arises* from the inner side of the coronoid process of the ulna, joining the preceding at an acute angle. The median nerve enters the forearm between the two heads of the muscle and is separated from the ulnar artery by the deep head. The muscle passes obliquely across the forearm from the inner to the outer side, and terminates in a flat tendon, which turns over the outer margin of the radius, and is *inserted* into a rough impression at the middle of the outer surface of the shaft of that bone.

FIG. 355.—Diagram showing attachments of the muscles of the forearm and hand. Anterior aspect. Origins, red; insertions, blue. The origins and insertions of the Palmar interosseous muscles are omitted. (See Fig. 151.)

Relations.—By its *superficial surface*, throughout the greater part of its extent, with the deep fascia; at its insertion the muscle is crossed by the radial vessels and nerve, and is covered by the Brachioradialis; by its *deep surface*, with the Brachialis anticus, Flexor sublimis digitorum, the median nerve, and ulnar artery, the small or deep head being interposed between the two latter structures. Its *outer border* forms the inner boundary of a triangular space (*antecubital space*) in which are placed the brachial artery, median nerve, and the tendon of the Biceps muscle. Its *inner border* is in contact with the Flexor carpi radialis.

Applied Anatomy.—This muscle, when suddenly brought into very active use, as in the game of lawn tennis, is liable to be strained, producing slight swelling and tenderness, and pain on putting the muscle into action. This is known as *lawn-tennis arm*.

The **Flexor carpi radialis** (*m. flexor carpi radialis*) lies on the inner side of the preceding muscle. It *arises* from the internal condyle by the common tendon, from the fascia of the forearm, and from the intermuscular septa between it and the Pronator teres, on the outside, the Palmaris longus internally, and the Flexor sublimis digitorum beneath. Slender and aponeurotic in structure at

its commencement, it increases in size, and terminates in a tendon which forms rather more than the lower half of its length. This tendon passes through a canal on the outer side of the annular ligament, runs through a groove in the os trapezium (which is converted into a canal by a fibrous sheath, and is lined with a synovial membrane), and is *inserted* into the base of the metacarpal bone of the index finger, and by a slip into the base of the metacarpal bone of the middle finger.

Relations.—By its *superficial surface*, with the deep fascia and the integument; by its *deep surface*, with the Flexor sublimis digitorum, Flexor longus pollicis, and wrist-joint; by its *outer border*, with the Pronator teres and the radial vessels; by its *inner border*, with the Palmaris longus above and the median nerve below.

The **Palmaris longus** (*m. palmaris longus*) (Fig. 356) is a slender, fusiform muscle, lying on the inner side of the preceding. It *arises* from the inner condyle of the humerus by the common tendon, from the deep fascia, and the intermuscular septa between it and the adjacent muscles. It terminates in a slender flattened tendon, which passes over the upper part of the annular ligament, to end in the central part of the palmar fascia and lower part of the annular ligament, frequently sending a tendinous slip to the short muscles of the thumb. This muscle is often absent, and is subject to very considerable variations; it may be tendinous above and muscular below; or it may be muscular in the centre, with a tendon above and below; or it may present two muscle bundles with a central tendon; or, finally, it may consist simply of a mere tendinous band.

Relations.—By its *superficial surface*, with the deep fascia. By its *deep surface*, with the Flexor sublimis digitorum. *Internally*, with the Flexor carpi ulnaris. *Externally*, with the Flexor carpi radialis. The median nerve lies close to the tendon, just above the wrist, on its inner and posterior side.

The **Flexor carpi ulnaris** (*m. flexor carpi ulnaris*) (Fig. 356) lies along the ulnar side of the forearm. It *arises* by two heads, connected by a tendinous arch, beneath which pass the ulnar nerve and posterior ulnar recurrent artery. One head (*caput humerale*) arises from the inner condyle of the humerus, by the common tendon; the other (*caput ulnare*), from the inner margin of the olecranon and from the upper two-thirds of the posterior border of the ulna, by an aponeurosis, common to it and the Extensor carpi ulnaris and Flexor profundus digitorum; and from the intermuscular septum between it and the Flexor sublimis digitorum. The fibres terminate in a tendon which occupies the anterior part of the lower half of the muscle, and is *inserted* into the pisiform bone, and is prolonged from this to the unciform and fifth metacarpal bones by the pisco-

FIG. 356.—Front of the left forearm. Superficial muscles.

unciform and pisometacarpal ligaments; it is also attached by a few fibres to the annular ligament.

Relations.—By its *superficial surface*, with the deep fascia, with which it is intimately connected for a considerable extent; by its *deep surface*, with the Flexor sublimis digitorum, the Flexor profundus digitorum, the Pronator quadratus, and the ulnar vessels and nerve; by its *outer or radial border*, with the Palmaris longus above and the ulnar vessels and nerve below.

The **Flexor sublimis digitorum** (*m. flexor digitorum sublimis*) (Fig. 356) is placed beneath the preceding muscles, which therefore must be removed in order to bring its attachment into view. It is the largest of the muscles of the superficial layer, and *arises* by three heads. One head (*caput humerale*) *arises* from the internal condyle of the humerus by the common tendon, from the internal lateral ligament of the elbow-joint, and from the intermuscular septum common to it and the preceding muscles. The second head (*caput ulnare*) *arises* from the inner side of the coronoid process of the ulna, above the ulnar origin of the Pronator teres (Fig. 145, p. 186). The third head (*caput radiale*) *arises* from the oblique line of the radius, extending from the tuberosity to the insertion of the Pronator teres. The fibres pass vertically downward, forming a broad and thick muscle, which speedily divides into two planes of muscle fibres, superficial and deep; the superficial plane divides into two parts which end in tendons for the middle and ring fingers; the deep plane also divides into two parts, which end in tendons for the index and little fingers, but previously to having done so it gives off a muscular slip, which joins that part of the superficial plane which is intended for the ring finger. As the four tendons thus formed pass beneath the annular ligament into the palm of the hand, they are arranged in pairs, the superficial pair corresponding to the middle and ring fingers, the deep pair to the index and little fingers. The tendons diverge from one another as they pass onward. Opposite the bases of the first phalanges each tendon divides into two slips (*chiasma tendinum*) to permit the passage of the corresponding tendon of the

FIG. 357.—Section passing through the middle third of the first phalanx of the middle finger (frozen section). The tendon of the Flexor sublimis digitorum is divided into two small bands, which spread laterally and engage themselves between the osseous plane and the Flexor profundus digitorum. (Poirier and Charpy.)

Flexor profundus digitorum; the two portions of the tendon then unite and form a grooved channel for the reception of the accompanying deep Flexor tendon. Finally, they subdivide a second time, to be *inserted* into the sides of the second phalanges about their middle. The insertion in the index finger is shown in Fig. 363. After leaving the palm the tendons of the superficial Flexor, accompanied by the deep Flexor tendons, lie in osseo-aponeurotic canals (Fig. 358). Each canal or *theca* extends from the metacarpophalangeal articulation to the proximal end of the distal phalanx (Fig. 257).

It is formed by strong fibrous bands, which arch across the tendons, and are attached on each side to the margins of the phalanges. Opposite the middle of the proximal and second phalanges the sheath is very strong, and the fibres pass transversely; but opposite the joints it is much thinner, and the fibres pass obliquely. It is very thin over the metacarpophalangeal articulation, and is absent over the distal phalanx. Each sheath is lined by a synovial membrane, which is reflected on the contained tendons.

Relations.—In the forearm, by its *superficial surface*, with the deep fascia and all the preceding superficial muscles; by its *deep surface*, with the Flexor profundus digitorum, Flexor

longus pollicis, the ulnar vessels and nerve, and the median nerve. In the hand its tendons are in relation, *superficially*, with the palmar fascia, superficial palmar arch, and the branches of the median nerve; *deeply*, with the tendons of the deep Flexor and the Lumbricales.

The Deep Layer (Fig. 358).

Flexor profundus digitorum.

Flexor longus pollicis.

Pronator quadratus.

Dissection.—Divide each of the superficial muscles at its centre, and turn either end aside; the deep layer of muscles, together with the median nerve and ulnar vessels, will then be exposed.

The **Flexor profundus digitorum** (*m. flexor digitorum profundus*) (Fig. 358) is situated on the ulnar side of the forearm, immediately beneath the superficial Flexors. It *arises* from the upper three-fourths of the anterior and inner surfaces of the shaft of the ulna, embracing the insertion of the Brachialis anticus above, and extending, below, to within a short distance of the Pronator quadratus. It also arises from a depression on the inner side of the coronoid process; by an aponeurosis from the upper three-fourths of the posterior border of the ulna, in common with the Flexor and Extensor carpi ulnaris; and from the ulnar half of the interosseous membrane. The fibres form a fleshy belly of considerable size, which divides into four tendons; these pass under the annular ligament beneath the tendons of the Flexor sublimis digitorum. Opposite the first phalanges the tendons pass through the openings in the tendons of the Flexor sublimis digitorum, and are finally *inserted* into the bases of the last phalanges. The portion of the muscle for the index finger (Fig. 362) is usually distinct throughout, but the tendons for the three inner fingers are connected by cellular tissue and tendinous slips as far as the palm of the hand. The tendons of this muscle and those of the Flexor sublimis digitorum, while contained in the osseaponeurotic canals of the fingers, are invested in a synovial sheath, and are connected to each other and to the phalanges by slender tendinous filaments, called **vincula accessoria tendinum** (*vincula tendineae*). Of these there are two sets: (a) The *ligamenta brevia*—two in each finger—are composed of triangular bands of fibres which connect respectively (1) the tendon of the Flexor sublimis digitorum to the front of the first interphalangeal joint, and (2) the head of the first phalanx and the tendon of the Flexor sublimis digitorum to the front of the second interphalangeal joint and to the head of the second phalanx. (b) The *ligamenta longa* connect the under surfaces of the Flexor profundus digitorum to those of the subjacent Flexor sublimis digitorum after the tendons of the former have passed through the latter (Fig. 363).

Four small muscles, the Lumbricales, are connected with the tendons of the Flexor profundus in the palm. They will be described with the muscles in that region.

Relations.—By its *superficial surface*, in the forearm, with the Flexor sublimis digitorum, the Flexor carpi ulnaris, the ulnar vessels, and nerve, and the median nerve; and in the hand, with the tendons of the superficial Flexor; by its *deep surface*, in the forearm, with the ulna, the interosseous membrane, the Pronator quadratus; and in the hand, with the Interossei, Adductor pollicis, and deep palmar arch; by its *ulnar border*, with the Flexor carpi ulnaris; by its *radial border*, with the Flexor longus pollicis, the anterior interosseous vessels and nerve being interposed.

The **Flexor longus pollicis** (*m. flexor pollicis longus*) (Fig. 358) is situated on the radial side of the forearm, lying on the same plane as the preceding. It *arises* from the grooved anterior surface of the shaft of the radius, commencing above,

FIG. 358.—Front of the left forearm.
Deep muscles.

FIG. 359.—Posterior surface of the left forearm
Superficial muscles.

immediately below the tuberosity and oblique line, and extending below to within a short distance of the Pronator quadratus. It also arises from the adjacent part of the interosseous membrane and generally by a fleshy slip from the inner border of the coronoid process or from the internal condyle of the humerus. The fibres pass downward, and terminate in a flattened tendon which passes beneath the annular ligament, is then lodged in the interspace between the superficial head of the Flexor brevis pollicis and the Adductor obliquus pollicis, and, entering an osseoponeurotic canal similar to those for the other Flexor tendons, is *inserted* into the base of the last phalanx of the thumb.

Relations.—By its *superficial surface*, with the Flexor sublimis digitorum, Flexor carpi radialis, Brachioradialis, and radial vessels; by its *deep surface*, with the radius, interosseous membrane, and Pronator quadratus; by its *ulnar border*, with the Flexor profundus digitorum, from which it is separated by the anterior interosseous vessels and nerve.

The **Pronator quadratus** (*m. pronator quadratus*) (Figs. 358 and 367) is a small, flat, quadrilateral muscle, extending transversely across the front of the radius and ulna, above their carpal extremities. It *arises* from the oblique ridge on the lower part of the anterior surface of the shaft of the ulna; from the lower fourth of the anterior surface and the anterior border of the ulna; and from a strong aponeurosis which covers the inner third of the muscle. The fibres pass outward and slightly downward, to be *inserted* into the lower fourth of the anterior surface and anterior border of the shaft of the radius.

Relations.—By its *superficial surface*, with the Flexor profundus digitorum, the Flexor longus pollicis, Flexor carpi radialis, and the radial vessels; by its *deep surface*, with the radius, ulna, and interosseous membrane.

Nerves.—All the muscles of the superficial layer are supplied by the median nerve, excepting the Flexor carpi ulnaris, which is supplied by the ulnar nerve. The Pronator teres and the Flexor carpi radialis derive their supply primarily from the sixth and seventh cervicals; the Palmaris longus from the eighth cervical; the Flexor sublimis digitorum from the seventh and eighth cervical and first thoracic, and the Flexor carpi ulnaris from the eighth cervical and first thoracic nerves. Of the deep layer, the Flexor profundus digitorum is supplied by the seventh and eighth cervicals and first thoracic through the ulnar and anterior interosseous branch of the median. The remaining two muscles, the Flexor longus pollicis and Pronator quadratus, are also supplied by the eighth cervical and first thoracic through the anterior interosseous branch of the median.

Actions.—These muscles act upon the forearm, the wrist, and hand. The Pronator teres helps to rotate the radius upon the ulna, rendering the hand prone; when the radius is fixed it assists the other muscles in flexing the forearm. The Flexor carpi radialis is one of the Flexors of the wrist; when acting alone it flexes the wrist, inclining it to the radial side. It can also assist in pronating the forearm and hand, and, by continuing its action, in bending the elbow. The Flexor carpi ulnaris is one of the flexors of the wrist; when acting alone it flexes the wrist, inclining it to the ulnar side (adducting the wrist), and, by continuing to contract, it bends the elbow. The Palmaris longus is a tensor of the palmar fascia. It also assists in flexing the wrist and elbow. The Flexor sublimis digitorum flexes first the middle and then the proximal phalanges. It assists in flexing the wrist and elbow. The Flexor profundus digitorum is one of the Flexors of the phalanges. After the Flexor sublimis has bent the second phalanx, the Flexor profundus flexes the terminal one, but it cannot do so until after the contraction of the superficial muscle. It also assists in flexing the wrist. The Flexor longus pollicis is the flexor of the distal phalanx of the thumb. When the thumb is fixed it also assists in flexing the wrist. The Pronator quadratus helps to rotate the radius upon the ulna, rendering the hand prone.

Applied Anatomy.—When a finger is amputated so that the fibrous sheath of the Flexor tendons is divided in a region in which it is firm and dense, the tendon contracts but the theca does not, and the rigid theca constitutes a permeable passage to the palm. If the parts should be infected the theca will draw pus toward the palm. Hence, it is best to close the theca by sutures. "Over the terminal phalanx, and over the joint between the middle and terminal phalanges, there is no fibrous sheath. In front of the metacarpophalangeal joint it is scarcely evident. Over the first and second (proximal and middle) phalanges, and in front of the joint between these bones, the fibrous sheath is well marked, and appears as a rigid tube when cut across. As the sheath crosses the metacarpophalangeal and first interphalangeal joints, it is adherent

the intermuscular septa between it and the adjacent muscles. The fibres terminate about the middle of the forearm in a flat tendon which is closely connected with that of the preceding muscle, and accompanies it to the wrist, lying in the same groove on the posterior surface of the radius; it passes beneath the Extensor tendons of the thumb, then beneath the annular ligament, and, diverging somewhat from its fellow, is *inserted* into the base of the metacarpal bone of the middle finger, on its radial side. There is often a bursa between a portion of the base of the bone and the tendon.

The tendons of the two preceding muscles pass through the same compartment of the annular ligament, and are lubricated by a single synovial membrane, but are separated from each other by a small vertical ridge of bone as they lie in the groove at the back of the radius.

Relations.—By its *superficial surface*, with the Extensor carpi radialis longior, and with the Extensor muscles of the thumb which cross it; by its *deep surface*, with the Supinator [brevis], tendon of the Pronator teres, radius, and wrist-joint; by its *ulnar border*, with the Extensor communis digitorum.

10. The Posterior Radioulnar Region (Fig. 359).

The muscles in this region are divided for purposes of description into two groups or layers, **superficial** and **deep**.

The Superficial Layer.

Extensor communis digitorum.
Extensor minimi digiti.

Extensor carpi ulnaris.
Anconeus.

The **Extensor communis digitorum** (*m. extensor digitorum communis*) is situated at the back part of the forearm. It *arises* from the external condyle of the humerus by the common tendon, from the deep fascia, and the intermuscular septa between it and the adjacent muscles. It divides below into four tendons which pass, together with that of the Extensor indicis, through a separate compartment of the annular ligament, lubricated by a synovial membrane. The tendons then diverge, pass across the back of the hand, and are *inserted* into the second and third phalanges of the fingers in the following manner: The *outermost* tendon, accompanied by the Extensor indicis, goes to the index finger (Figs. 359 and 362); the *second* tendon is sometimes connected to the first by a thin transverse band, and receives a slip from the third tendon (Fig. 359); it goes to the middle finger; the *third* tendon gives off the slip to the second (Fig. 359), and receives a very considerable part of the fourth tendon; the *fourth*, or *innermost* tendon, divides into two parts; one goes to join the third tendon, the other, reinforced by the Extensor minimi digiti, goes to the little finger. Each tendon opposite the metacarpophalangeal articulation becomes narrow and thickened, and gives off a thin fasciculus upon each side of the joint, which blends with the lateral ligaments and serves as the posterior ligament; after having passed the joint it spreads out into a broad aponeurosis, which covers the whole of the dorsal surface of the first phalanx, being reinforced, in this situation, by the tendons of the Interossei and Lumbricales. Opposite the first phalangeal joint this aponeurosis divides into three slips, a middle and two lateral; the former is *inserted* into the base of the second phalanx, and the two lateral, which are continued onward along the sides of the second phalanx, unite by their contiguous margins, and are *inserted* into the dorsal surface of the last phalanx. As the tendons cross the phalangeal joints they furnish them with posterior ligaments. The accessory

slips or **lateral vincula** which join the tendon of the ring finger to the tendon of the little finger and to the tendon of the middle finger are constant. If the middle and little fingers are held flexed the lateral vincula greatly limit the range of extension possible in the ring finger.

Relations.—By its *superficial surface*, with the fascia of the forearm and hand, the posterior annular ligament, and integument; by its *deep surface*, with the Supinator [brevis], the Extensor muscles of the thumb and index finger, the posterior interosseous vessels and nerve, the wrist-joint, carpus, metacarpus, and phalanges; by its *radial border*, with the Extensor carpi radialis brevis; by its *ulnar border*, with the Extensor minimi digiti and Extensor carpi ulnaris.

FIG. 360.—Diagram showing attachments of muscles of forearm and hand. Posterior aspect. Origins, red; insertions, blue. The origins and insertions of the Dorsal interossei muscles are omitted. (See Fig. 150.)

The **Extensor minimi digiti** (*m. extensor digiti quinti proprius*) is a slender muscle placed on the inner side of the Extensor communis, with which it is generally connected. It arises from the common Extensor tendon by a thin, tendinous slip, and from the intermuscular septa between it and the adjacent muscles. Its tendon runs through a separate compartment in the annular ligament behind the inferior radioulnar joint, then divides into two as it crosses the hand, the outermost division being joined by the slip from the innermost tendon of the common Extensor. The two slips thus formed spread into a broad aponeurosis, which, after receiving a slip from the Abductor minimi digiti, is inserted into the second and third phalanges of the little finger. The tendon is situated on the ulnar side of, and is somewhat more superficial than, the common Extensor.

The **Extensor carpi ulnaris** is the most superficial muscle on the ulnar side of the forearm. It *arises* from the external condyle of the humerus by the common Extensor tendon; by an aponeurosis from the posterior border of the ulna in common with the Flexor carpi ulnaris and the Flexor profundus digitorum; and from the deep fascia of the forearm. This muscle terminates in a tendon which runs through a groove behind the styloid process of the ulna, passes through a separate compartment in the annular ligament, and is *inserted* into the prominent tubercle on the ulnar side of the base of the metacarpal bone of the little finger.

The **Anconeus** (*m. anconaeus*) is a small triangular muscle placed behind and below the elbow-joint, and appears to be a continuation of the external portion of the Triceps. It *arises* by a separate tendon from the back part of the outer condyle of the humerus, and is *inserted* into the side of the olecranon and upper fourth of the posterior surface of the shaft of the ulna; its fibres diverge from their origin, the upper ones being directed transversely, the lower obliquely inward.

The Deep Layer (Fig. 362).

Supinator [brevis].

Extensor brevis pollicis.

Extensor ossis metacarpi pollicis.

Extensor longus pollicis.

Extensor indicis.

The **Supinator [brevis]** (*m. supinator*) (Figs. 361 and 362) is a broad muscle, of hollow cylindrical form, curved around the upper third of the radius. It consists of two distinct planes of muscle fibres, between which lies the posterior interosseous nerve (Fig. 361). The two planes *arise* in common—the superficial one by tendinous, and the deeper by muscle, fibres from the external condyle of the humerus, from the external lateral ligament of the elbow-joint and the orbicular ligament of the radius; from the ridge on the ulna, which runs obliquely downward from the posterior extremity of the lesser sigmoid cavity; from the triangular depression in front of the cavity; and from a tendinous expansion which covers the surface of the muscle. The superficial fibres surround the upper part of the radius, and are *inserted* into the outer edge of the bicipital tuberosity and into the oblique line of the radius, as low down as the insertion of the Pronator teres. The upper fibres of the deeper plane form a sling-like fasciculus, which encircles the neck of the radius above the tuberosity and is attached to the back part of its inner surface; the greater part of this portion of the muscle is *inserted* into the posterior and external surface of the shaft, midway between the oblique line and the head of the bone. Between the insertion of the two planes the posterior interosseous nerve lies on the shaft of the bone (Fig. 361).

Relations.—By its *superficial surface*, with the superficial Extensors and the Brachioradialis muscles, and the radial vessels and nerve; by its *deep surface*, with the elbow-joint, the interosseous membrane, and the radius.

The **Extensor ossis metacarpi pollicis** (*m. abductor pollicis longus*) is the most external and the largest of the deep Extensor muscles; it lies immediately below the Supinator [brevis], with which it is sometimes united. It *arises* from the outer part of the posterior surface of the shaft of the ulna below the insertion of the Anconeus, from the interosseous membrane, and from the middle third of the posterior surface of the shaft of the radius. Passing obliquely downward and outward, it terminates in a tendon which runs through a groove on the outer side of the styloid process of the radius, accompanied by the tendon of the Extensor brevis pollicis, and is *inserted* into the base of the metacarpal bone of the thumb.

It occasionally gives off two slips near its insertion—one to the trapezium, and the other to blend with the origin of the Abductor pollicis.

FIG. 361.—Supinator [brevis]. (From a preparation in the Museum of the Royal College of Surgeons of England.)

Relations.—By its *superficial surface*, with the Extensor communis digitorum, Extensor minimi digiti, and fascia of the forearm, and with the branches of the posterior interosseous artery and nerve which cross it; by its *deep surface*, with the ulna, the interosseous membrane, the radius, the tendons of the Extensor carpi radialis longior and brevior, which it crosses obliquely, and at the outer side of the wrist, with the radial vessels; by its *upper border*, with the Supinator [brevis]; by its *lower border*, with the Extensor brevis pollicis.

The **Extensor brevis pollicis** (*m. extensor pollicis brevis*), the smallest muscle of this group, lies on the inner side of the preceding. It arises from the posterior surface of the shaft of the radius, below the Extensor ossis metacarpi pollicis, and from the interosseous membrane. Its direction is similar to that of the Extensor ossis metacarpi

FIG. 362.—Posterior surface of the left forearm. Deep muscles.

pollicis, its tendon passing through the same groove on the outer side of the styloid process, to be *inserted* into the base of the first phalanx of the thumb.

Relations.—The same as those of the Extensor ossis metacarpi pollicis.

The **Extensor longus pollicis** (*m. extensor pollicis longus*) is much larger than the preceding muscle, the origin of which it partly covers in. It *arises* from the outer part of the posterior surface of the shaft of the ulna, below the origin of the Extensor ossis metacarpi pollicis, and from the interosseous membrane. It terminates in a tendon which passes through a separate compartment

FIG. 363.—The tendons attached to the right index finger.

in the annular ligament, lying in a narrow, oblique groove at the back part of the lower end of the radius. It then crosses obliquely the tendons of the Extensor carpi radialis longior and breviar, being separated from the other Extensor tendons of the thumb, by a triangular interval, in which the radial artery is found, and is finally *inserted* into the base of the last phalanx of the thumb.

Relations.—By its *superficial surface*, with the same parts as the Extensor ossis metacarpi pollicis; by its *deep surface*, with the ulna, interosseous membrane, the posterior interosseous nerve, radius, the wrist, the radial vessels, and metacarpal bone of the thumb.

The **Extensor indicis** (*m. extensor indicis proprius*) (Figs. 359 and 362) is a narrow, elongated muscle placed on the inner side of, and parallel with, the

preceding. It *arises* from the posterior surface of the shaft of the ulna, below the origin of the Extensor longus pollicis and from the interosseous membrane. Its tendon passes with the Extensor communis digitorum through the same canal in the annular ligament, and subsequently joins the tendon of the Extensor communis which belongs to the index finger, opposite the lower end of the corresponding metacarpal bone, lying to the ulnar side of the tendon from the common Extensor.

Nerves.—The Brachioradialis is supplied by the fifth and sixth, the Extensor carpi radialis longior by the sixth and seventh, and the Anconeus by the seventh and eighth cervical nerves, all through the musculospiral nerve; the remaining muscles of the radial and posterior brachial region are supplied through the posterior interosseous nerve, the Supinator [brevis] being supplied by the sixth cervical, the Extensor carpi radialis brevis by the sixth and seventh cervicals, and all the other muscles by the seventh cervical.

Actions.—The muscles of the radial and posterior brachial regions, which comprise all the Extensor and Supinator muscles, act upon the forearm, wrist, and hand; they are the direct antagonists of the Pronator and Flexor muscles. The Anconeus assists the Triceps in extending the forearm. The chief action of the Brachioradialis is that of a Flexor of the elbow-joint, but in addition to this it may act both as a Supinator or a Pronator; that is to say, if the forearm is forcibly pronated it will act as a Supinator, and bring the bones into a position midway between supination and pronation; and, *vice versa*, if the arm is forcibly supinated, it will act as a pronator, and bring the bones into the same position, midway between supination and pronation. The action of the muscle is therefore to throw the forearm and hand into the position they naturally occupy when placed across the chest. The Supinator [brevis] is a true supinator; that is to say, when the radius has been carried across the ulna in pronation and the back of the hand is directed forward, this muscle carries the radius back again to its normal position on the outer side of the ulna, and the palm of the hand is again directed forward. The Extensor carpi radialis longior extends the wrist and abducts the hand. It may also assist in bending the elbow-joint; at all events, it serves to fix or steady this articulation. The Extensor carpi radialis brevis assists the Extensor carpi radialis longior in extending the wrist, and may also act slightly as an abductor of the hand. The Extensor carpi ulnaris helps to extend the hand, but when acting alone inclines it toward the ulnar side; by its continued action it extends the elbow-joint. The Extensor communis digitorum extends the phalanges, then the wrist, and finally the elbow. It acts principally on the proximal phalanges, the middle and terminal phalanges being extended by the Interossei and Lumbricales. It has also a tendency to separate the fingers as it extends them. The Extensor minimi digiti extends similarly the little finger, and by its continued action it assists in extending the wrist. It is owing to this muscle that the little finger can be extended or pointed while the others are flexed. The chief action of the Extensor ossis metacarpi pollicis is to carry the thumb outward and backward from the palm of the hand, and hence it has been called the **Abductor pollicis longus**. By its continued action it helps to extend and abduct the wrist. The Extensor brevis pollicis extends the proximal phalanx of the thumb. By its continued action it helps to extend and abduct the wrist. The Extensor longus pollicis extends the terminal phalanx of the thumb. By its continued action it helps to extend and abduct the wrist. The Extensor indicis extends the index finger, and by its continued action assists in extending the wrist. It is owing to this muscle that the index finger can be extended or pointed while the others are flexed.

Applied Anatomy.—The tendons of the Extensor muscles of the thumb are liable to become strained and their sheaths inflamed after excessive exercise, producing a sausage-shaped swelling along the course of the tendon, and giving a peculiar creaking sensation to the finger when the muscle acts; it is known as *tenosynovitis*. In piano-players the slips which join the tendons of the Extensor communis digitorum may limit freedom of motion in individual fingers. Their complete extension, without operative interference, can only be brought about by long-continued exertion in practice, when elongation of certain accessory, but restricting, tendons is made by nutritive growth. If there is much limitation, division of the hindering slips is advisable.¹ Paralysis of the Extensor muscles of the hand is common in lead poisoning, and causes the well-known "*wrist drop*." Curiously enough, the Brachioradialis and Extensor ossis metacarpi pollicis muscles escape. The paralysis is due to a neuritis of the musculospiral nerve.

¹ Prof. William S. Forbes, in the Philadelphia Medical Journal, January 15, 1898.

IV. MUSCLES AND FASCIÆ OF THE HAND.

The muscles of the hand are subdivided into three groups: (1) Those of the thumb, which occupy the radial side and produce the **thenar eminence**. (2) Those of the little finger, which occupy the ulnar side and give rise to the **hypothenar eminence**. (3) Those in the middle of the palm and within the interosseous spaces.

Dissection (Fig. 346).—Make a transverse incision across the front of the wrist, and a second across the heads of the metacarpal bones; connect the two by a vertical incision in the middle line, and continue it through the centre of the middle finger. The anterior and posterior annular ligaments and the palmar fascia should then be dissected.

FIG. 364.—Transverse section through the carpus, showing the relative positions of the tendons, vessels, and nerves. (Henle.)

The **Anterior Annular Ligament** (*ligamentum carpi transversum*) (Fig. 364) is a strong, fibrous band which arches over the carpus, converting the deep groove on the front of the carpal bones into a canal, beneath which pass the Flexor tendons of the fingers. It is attached, internally, to the pisiform bone and the hook of the ulnar bone, and externally to the tuberosity of the scaphoid and to the inner part of the anterior surface and the ridge of the trapezium. It is continuous, *above*, with the deep fascia of the forearm, of which it may be regarded as a thickened portion, and, *below*, with the palmar fascia. It is crossed by the ulnar vessels and nerve and the cutaneous branches of the median and ulnar nerves. At its outer extremity is the tendon of the Flexor carpi radialis, which lies in the groove on the trapezium between the attachments of the annular ligaments to the bone. It has inserted into its anterior surface a part of the tendon of the Palmaris longus and part of the tendon of the Flexor carpi ulnaris, and has arising from it, below, the small muscles of the thumb and little finger. Beneath it pass the tendons of the Flexores sublimis and Profundus digitorum, the tendon of the Flexor longus pollicis, and the median nerve.

The Synovial Membranes of the Flexor Tendons at the Wrist.—There are two vaginal synovial membranes which enclose all the tendons as they pass beneath this ligament—one for the Flexores sublimis and Profundus digitorum, the other for the Flexor longus pollicis. They extend up into the forearm for about an inch above the annular ligament, and downward about half-way along the metacarpal bone, where they terminate in a blind diverticulum around each pair

of tendons, with the exception of those of the thumb and little finger; in each of these two digits the diverticulum is continued on, and communicates with the synovial sheath of the tendons in the fingers. In the other three fingers the synovial sheath of the tendons begins as a blind pouch without communication with the large synovial sac (Fig. 365).

Applied Anatomy.—This arrangement of the synovial sheaths explains the fact that thecal abscess in the thumb or little finger is liable to be followed by abscesses of the forearm, from extension of the inflammation along the continuous synovial sheaths. Tuberculous inflammation is liable to occur in this situation, constituting *compound palmar ganglion*; it presents an hour-glass outline, with a swelling in front of the wrist and in the palm of the hand, and a constriction corresponding to the annular ligament between the two. The fluid can be forced from the one swelling to the other under the ligament.

FIG. 365.—Diagram showing the arrangement of the synovial sheaths of the palm and fingers.

FIG. 366.—Transverse section through the wrist, showing the annular ligaments and the canals for the passage of the tendons.

Bursæ about the Hand and Wrist.—

Bursæ usually exist between the distal extremities of the metacarpal bones (*bursæ intermetacarpophalangeæ*), and a subcutaneous bursa often exists over the dorsal surface of the head of the fifth metacarpal bone. Subcutaneous digital dorsal bursæ occur "almost constantly in the first finger-joints (between the first and second phalanx), occasionally in the second joint of the second and fourth fingers" (*bursæ subcutaneæ digitorum dorsales*). A bursa exists between the tendon of the Extensor carpi radialis brevis and the base of the third metacarpal bone; another between the Flexor carpi ulnaris and the pisiform bone; another between the Flexor carpi radialis and the base of the second metacarpal bone.

The **Posterior Annular Ligament** (*ligamentum carpi dorsale*) is a strong fibrous band extending obliquely downward and inward across the back of the wrist, and consisting of the deep fascia of the back of the forearm, strengthened by the addition of some transverse fibres. It binds down the Extensor tendons in their passage to the fingers, being attached, *internally*, to the styloid process of the ulna, the cuneiform and pisiform bones; *externally*, to the margin of the radius; and, in its passage across the wrist, to the ridges on the posterior surface of the radius. It presents six compartments for the passage of tendons, each of which is lined with a separate synovial membrane (Fig. 366). These are, from without inward: (1) On the outer side of the styloid process, for the tendons of the Extensor ossis metacarpi and Extensor brevis pollicis. (2) Behind the styloid process, for the tendons of the Extensor carpi radialis longior and

brevior. (3) About the middle of the posterior surface of the radius, for the tendon of the Extensor longus pollicis. (4) To the inner side of the latter, for the tendons of the Extensor communis digitorum and Extensor indicis. (5) Opposite the interval between the radius and ulna, for the Extensor minimi digiti. (6) Grooving the back of the ulna, for the tendon of the Extensor carpi ulnaris. The synovial membranes lining these sheaths are usually very extensive, reaching from above the annular ligament down upon the tendons for a variable distance on the back of the hand.

FIG. 367.—Palmar fascia. (From a preparation in the Museum of the Royal College of Surgeons of England.)

The **deep palmar fascia** (*aponeurosis palmaris*) (Fig. 367) forms a common sheath which invests the muscles of the hand. It consists of a **central** and **two lateral portions**.

The **central portion** occupies the middle of the palm, is triangular in shape, of great strength and thickness, and binds down the tendons and protects the vessels and nerves in this situation. It is narrow *above*, where it is attached to the lower margin of the annular ligament, and receives the expanded tendon of the Palmaris longus muscle. *Below*, it is broad and expanded, and divides into four slips for the four fingers. Each slip gives off superficial fibres, which are inserted

into the skin of the palm and finger, those to the palm joining the skin at the furrow corresponding to the metacarpophalangeal articulation, and those to the fingers passing into the skin at the transverse fold at the base of the fingers. The deeper part of each slip subdivides into two processes, which are inserted into the lateral margins of the anterior ligament of the metacarpophalangeal joint. From the sides of these processes portions are sent backward to be attached to the borders of the lateral surfaces of the metacarpal bones at their distal extremities. By this arrangement short channels are formed on the front of the lower ends of the metacarpal bones, through which the Flexor tendons pass.¹ The intervals left in the fascia between the four fibrous slips transmit the digital vessels and nerves and the tendons of the Lumbricales. At the points of division of the palmar fascia into the slips above mentioned numerous strong, transverse fibres bind the separate processes together. The palmar fascia is intimately adherent to the integument by dense, fibroareolar tissue, forming the superficial palmar fascia, and gives origin by its inner margin to the Palmaris brevis; it covers the superficial palmar arch, the tendons of the Flexor muscles, and the branches of the median and ulnar nerves, and on each side it gives off a vertical septum, which is continuous with the interosseous aponeurosis and separates the two lateral from the middle palmar group of muscles.

The lateral portions of the palmar fascia are thin, fibrous layers, which cover, on the radial side, the muscles of the ball of the thumb, and, on the ulnar side, the muscles of the little finger; they are continuous with the dorsal fascia, and in the palm with the central portion of the palmar fascia.

The **Superficial Transverse Ligament of the Fingers** is a thin band of transverse fibres (*fasciculi transversi*); it stretches across the roots of the four fingers, and is closely attached to the skin of the clefts, and internally to the fifth metacarpal bone, forming a sort of rudimentary web. Beneath it the digital vessels and nerves pass onward to their destination.

Applied Anatomy.—The palmar fascia is liable to undergo contraction, producing a very inconvenient deformity known as *Dupuytren's contraction*. The ring and little fingers are most frequently implicated, but the middle, the index, and the thumb may be involved. The proximal phalanx is flexed and cannot be straightened, and the two distal phalanges become similarly flexed as the disease advances.

11. The Radial Region (Figs. 368, 369).

Abductor pollicis.

Flexor brevis pollicis.

Opponens pollicis.

Adductor obliquus pollicis.

Adductor transversus pollicis.

The **Abductor pollicis** (*m. abductor pollicis brevis*) (Fig. 359) is a thin, flat muscle, placed immediately beneath the integument. It arises from the anterior annular ligament, the tuberosity of the scaphoid, and the ridge of the trapezium, frequently by two distinct slips; and, passing outward and downward, is inserted by a thin, flat tendon into the radial side of the base of the first phalanx of the thumb, sending a slip to join the tendon of the Extensor longus pollicis.

Relations.—By its *superficial surface*, with the palmar fascia and superficialis volae artery, which frequently perforates it. By its *deep surface*, with the Opponens pollicis. Its *inner border* is separated from the Flexor brevis pollicis by a narrow cellular interval.

¹ Dr. Keen describes a fifth slip as frequently found passing to the thumb.

The **Opponens pollicis** (*m. opponens pollicis*) (Figs. 368 and 369) is placed beneath and partially to the outer side of the preceding. It arises from the ridge on the trapezium and from the anterior annular ligament, passes downward and outward, and is inserted into the whole length of the metacarpal bone of the thumb on its radial side.

FIG. 368.—Adductor pollicis, Opponens pollicis, and Pronator quadratus. (Testut.)

Relations.—By its *superficial surface*, with the Abductor and Flexor brevis pollicis. By its *deep surface*, with the first metacarpal bone. By its *inner border*, with the Adductor obliquus pollicis.

The **Flexor brevis pollicis** (*m. flexor pollicis brevis*) (Fig. 369) consists of two portions, superficial and deep. The **superficial portion** arises from the outer two-thirds of the lower border of the anterior annular ligaments, and passes along

The **Adductor obliquus pollicis** (*m. adductor pollicis*) (Figs. 368 and 369) *arises* by several slips from the os magnum, the bases of the second and third metacarpal bones, the anterior carpal ligaments, and the sheath of the tendon of the Flexor carpi radialis. From this origin the greater number of fibres pass obliquely downward and converge to a tendon, which, uniting, with the tendons of the deeper portion of the Flexor brevis pollicis and the Adductor transversus, is *inserted* into the inner side of the base of the first phalanx of the thumb, a sesamoid bone being developed in the tendon of insertion. A considerable fasciculus, however, passes more obliquely outward beneath the tendon of the long Flexor to join the superficial portion of the short Flexor and the Abductor pollicis.¹

Relations.—By its *superficial surface*, with the Flexor longus pollicis and the superficial head of the Flexor brevis pollicis. Its *deep surface* is in relation with the deep palmar arch, which passes between the two Adductors.

The **Adductor transversus pollicis** (*m. adductor transversus pollicis*) (Figs. 368 and 369) is the most deeply seated of this group of muscles. It is of a triangular form, *arising*, by its broad base, from the lower two-thirds of the metacarpal bone of the middle finger on its palmar surface; the fibres, proceeding outward, converge to be *inserted*, with the inner part of the Flexor brevis pollicis, and the Adductor obliquus pollicis, into the ulnar side of the base of the first phalanx of the thumb. From the common tendon of insertion a slip is prolonged to the Extensor longus pollicis.

Relations.—By its *superficial surface*, with the tendons of the Flexor profundus and the Lumbricales. Its *deep surface* covers the first two interosseous spaces, from which it is separated by a strong aponeurosis.

Three of these muscles of the thumb, the Abductor, the Adductor transversus, and the Flexor brevis pollicis, at their insertions give off fibrous expansions which join the tendon of the Extensor longus pollicis. This permits of flexion of the proximal phalanx and extension of the terminal phalanx at the same time.

Nerves.—The Abductor, Opponens, and superficial head of the Flexor brevis pollicis are supplied by the sixth cervical through the median nerve; the deep head of the Flexor brevis, and the Adductors, by the eighth cervical through the ulnar nerve.

Actions.—The actions of the muscles of the thumb are almost sufficiently indicated by their names. This segment of the hand is provided with three Extensors—an Extensor of the metacarpal bone, an Extensor of the first, and an Extensor of the second phalanx; these occupy the dorsal surface of the forearm and hand. There are also three Flexors on the palmar surface—a Flexor of the metacarpal bone, a Flexor of the proximal, and a Flexor of the terminal phalanx; there is also an Abductor and two Adductors. The Abductor pollicis moves the metacarpal bone of the thumb outward; that is, away from the index finger. The Opponens pollicis flexes the metacarpal bones—that is, draws it inward over the palm—so as to turn the ball of the thumb toward the fingers, thus producing the movement of opposition. The Flexor brevis pollicis flexes and adducts the proximal phalanx of the thumb. The Adductores pollicis move the metacarpal bone of the thumb inward; that is, toward the index finger. These muscles give to the thumb its extensive range of motion. It will be noticed, however, that in consequence of the position of the first metacarpal bone, these movements differ from the corresponding movements of the metacarpal bones of the other fingers. Thus extension of the thumb more nearly corresponds to the motion of abduction in the other fingers, and flexion to adduction.

12. The Ulnar Region (Fig. 369).

Palmaris brevis.

Abductor minimi digiti.

Flexor brevis minimi digiti.

Opponens minimi digiti.

The **Palmaris brevis** (*m. palmaris brevis*) is a thin quadrilateral muscle placed beneath the integument on the ulnar side of the hand. It *arises* by tendinous

¹ This muscle is described by some as the deep portion of the Flexor brevis pollicis.

fasciculi from the anterior annular ligament and palmar fascia; the fleshy fibres pass inward, to be *inserted* into the skin on the inner border of the palm of the hand.

The **Abductor minimi digiti** (*m. abductor digiti quinti*) is situated on the ulnar border of the palm of the hand. It *arises* from the pisiform bone and from the tendon of the Flexor carpi ulnaris, and terminates in a flat tendon, which divides into two slips; one is *inserted* into the ulnar side of the base of the first phalanx of the little finger. The other slip is *inserted* into the ulnar border of the aponeurosis of the Extensor minimi digiti.

Relations.—By its *superficial surface*, with the inner portion of the palmar fascia and the Palmaris brevis; by its *deep surface*, with the Opponens minimi digiti; by its *outer border*, with the Flexor brevis minimi digiti.

The **Flexor brevis minimi digiti** (*m. flexor digiti quinti brevis*) lies on the same plane as the preceding muscle, on its radial side. It *arises* from the convex aspect of the hook of the unciform bone and anterior surface of the annular ligament, and is *inserted* into the inner side of the base of the first phalanx of the little finger. It is separated from the Abductor at its origin by the deep branches of the ulnar artery and nerve. This muscle is sometimes wanting; the Abductor is then, usually, of large size.

Relations.—By its *superficial surface*, with the internal portion of the palmar fascia and the Palmaris brevis; by its *deep surface*, with the Opponens. The deep branch of the ulnar artery and the corresponding branch of the ulnar nerve pass between the Abductor and Flexor brevis minimi digiti muscles.

The **Opponens minimi digiti** (*m. opponens digiti quinti*) (Fig. 358) is of a triangular form, and placed immediately beneath the preceding muscles. It *arises* from the convexity of the hook of the unciform bone and the contiguous portion of the anterior annular ligament; its fibres pass downward and inward, to be *inserted* into the whole length of the metacarpal bone of the little finger, along its ulnar margin.

Relations.—By its *superficial surface*, with the Flexor brevis and Abductor minimi digiti; by its *deep surface*, with the Interossei muscles in the fourth metacarpal space, the metacarpal bone, and the Flexor tendons of the little finger.

Nerves.—All the muscles of this group are supplied by the eighth cervical nerve through the ulnar nerve.

Actions.—The Abductor minimi digiti abducts the little finger from the middle line of the hand. It corresponds to a dorsal interosseous muscle. It also assists in flexing the proximal phalanx and extending the second and third phalanges. The Flexor brevis minimi digiti abducts the little finger from the middle line of the hand. It also assists in flexing the proximal phalanx. The Opponens minimi digiti draws forward the fifth metacarpal bone, so as to deepen the hollow of the palm. The Palmaris brevis corrugates the skin on the inner side of the palm of the hand and probably serves to protect the ulnar nerve and artery from damage by the pressure of grasping a hard object.

13. The Middle Palmar Region.

Lumbricales.

Interossei dorsales.

Interossei palmares.

The **Lumbricales** (*mm. lumbricales*) (Fig. 369) are four small fleshy fasciculi, accessories to the deep Flexor muscle. They *arise* from the tendons of the Flexor profundus digitorum; the *first* and *second*, from the radial side and palmar surface of the tendons of the index and middle fingers, respectively; the *third*, from the contiguous sides of the tendons of the middle and ring fingers; and the

fourth, from the contiguous sides of the tendons of the ring and little fingers. They pass to the radial side of the corresponding fingers and opposite the metacarpophalangeal articulation each tendon is *inserted* into the tendinous expansion of the Extensor communis digitorum, covering the dorsal aspect of each finger.

The **Interossei muscles** (*mm. interossei*) (Figs. 370 and 371) are so named from occupying the intervals between the metacarpal bones, and are divided into two sets, dorsal and palmar.

FIG. 370.—The Dorsal interossei of left hand. The line marked by an * is that from which abduction is made.

FIG. 371.—The Palmar interossei of left hand. The line marked by an * is that to which adduction is made.

The **Dorsal interossei** (*mm. interossei dorsales*) are four in number, larger than the palmar, and occupy the intervals between the metacarpal bones. They are bipenniform muscles, *arising* by two heads from the adjacent sides of the metacarpal bones, but more extensively from the metacarpal bone of the finger into which the muscle is inserted. They are *inserted* into the bases of the first phalanges and into the aponeurosis of the common Extensor tendon. Between the double origin of each of these muscles is a narrow triangular interval, through the first of which passes the radial artery; through each of the other three passes a perforating branch from the deep palmar arch.

The **First dorsal interosseous muscle**, or **Abductor indicis**, is larger than the others. It is flat, triangular in form, and *arises* by two heads, separated by a fibrous arch, for the passage of the radial artery from the dorsum to the palm of the hand. The **outer head** *arises* from the upper half of the ulnar border of the first metacarpal bone; the **inner head**, from almost the entire length of the radial border of the second metacarpal bone; the tendon is *inserted* into the radial side of the index finger. The **Second** and **Third dorsal interossei** are *inserted* into the middle finger, the former into its radial, the latter into its ulnar side. The **Fourth** is *inserted* into the ulnar side of the ring finger.

The **Palmar interossei** (*mm. interossei volares*), three in number, are smaller than the Dorsal, and placed upon the palmar surface of the metacarpal bones, rather than between them. Each muscle *arises* from the entire length of the metacarpal bone of one finger, and is *inserted* into the side of the base of the first

phalanx and aponeurotic expansion of the common Extensor tendon of the same finger. The **First** arises from the ulnar side of the second metacarpal bone, and is inserted into the same side of the first phalanx of the index finger. The **Second** arises from the radial side of the fourth metacarpal bone, and is inserted into the same side of the ring finger. The **Third** arises from the radial side of the fifth metacarpal bone, and is inserted into the same side of the little finger. From this account it may be seen that each finger is provided with two Interosseous muscles, with the exception of the little finger, in which the Abductor muscle takes the place of one of the pair.

Nerves.—The two outer Lumbricales are supplied by the sixth cervical nerve, through the third and fourth digital branches of the median nerve; the two inner Lumbricales and all the Interossei are supplied by the eighth cervical nerve, through the deep palmar branch of the ulnar nerve. The third Lumbrical frequently receives a twig from the median.

Actions.—The Palmar interossei muscles adduct the finger to an imaginary line drawn longitudinally through the centre of the middle finger; and the Dorsal interossei abduct the fingers from that line. In addition to this, the Interossei, in conjunction with the Lumbricales, flex the first phalanges at the metacarpophalangeal joints, and extend the second and third phalanges in consequence of their insertion into the expansion of the Extensor tendons. The Extensor communis digitorum is believed to act almost entirely on the first phalanges.

SURFACE FORM OF THE UPPER EXTREMITY.

The **Pectoralis major muscle** largely influences surface form and conceals a considerable part of the thoracic wall in front. Its sternal origin presents a festooned border which bounds and determines the width of the sternal furrow. Its clavicular origin is somewhat depressed and flattened, and between the two portions of the muscle is often an oblique depression which differentiates the one from the other. The outer margin of the muscle is generally well marked above, and bounds the *infraclavicular fossa* (Fossa of Mohrenheim), a triangular interval which separates the Pectoralis major from the Deltoid. It gradually becomes less marked as it approaches the tendons of insertion, and becomes more closely blended with the Deltoid muscle. The lower border of the Pectoralis major forms the rounded *anterior axillary fold*, and corresponds with the direction of the fifth rib. The **Pectoralis minor muscle** influences surface form. When the arm is raised its lowest slip of origin produces a local fulness just below the border of the anterior fold of the axilla, and so serves to break the sharp line of the lower border of the Pectoralis major muscle, which is produced when the arm is in this position. The origin of the **Serratus magnus muscle** produces a very characteristic surface marking. When the arm is raised from the side in a well-developed subject, the five or six lower serrations are plainly discernible, forming a zigzag line, caused by the series of digitations, which diminish in size from above downward, and have their apices arranged in the form of a curve. When the arm is lying by the side, the first serration to appear, at the lower margin of the Pectoralis major, is the one attached to the fifth rib. The **Deltoid muscle**, with the prominence of the upper extremity of the humerus, produces the rounded outline of the shoulder. It is rounder and fuller in front than behind, where it presents a somewhat flattened form. Its anterior border, above, presents a rounded, slightly curved eminence, which bounds externally the infraclavicular fossa; below, it is closely united with the Pectoralis major. Its posterior border is thin, flattened, and scarcely marked above; below, it is thicker and more prominent. When the muscle is in action, the middle portion becomes irregular, presenting alternate longitudinal elevations and depressions, the elevations corresponding to the fleshy portions, the depressions to the tendinous intersections of the muscle. The insertion of the Deltoid is marked by a depression on the outer side of the middle of the arm. Of the scapular muscles, the only one which materially influences surface form is the **Teres major**, which assists the Latissimus dorsi in forming the thick, rounded fold of the *posterior boundary of the axilla*. When the arm is raised, the **Coracobrachialis** reveals itself as a long, narrow elevation which emerges from under cover of the anterior fold of the axilla and runs downward, internal to the shaft of the humerus. When the arm is hanging by the side, its front and inner part presents the prominence of the **Biceps**, bounded on either side by an intermuscular depression. This muscle determines the contour of the front of the arm, and extends from the anterior margin of the axilla to the bend of the elbow. Its upper tendons are concealed by the Pectoralis major and the Deltoid, and its lower tendon sinks into the space at the bend of the elbow. When the muscle is in a state of complete contraction—that is to say, when the forearm has been flexed and supinated—it presents a rounded convex form, bulged out laterally, and its length is diminished. On each side of the Biceps,

at the lower part of the arm, the **Brachialis anticus** is discernible. On the outer side it forms a narrow eminence which extends some distance up the arm along the border of the Biceps. On the inner side it shows itself only as a little fulness just above the elbow. On the back of the arm the long head of the **Triceps** may be seen as a longitudinal eminence emerging from under cover of the Deltoid, and gradually merging into the longitudinal flattened plane of the tendon of the muscle on the lower part of the back of the arm. The tendon of insertion of the muscle extends about half-way up the back of the arm, where it forms an elongated flattened plane when the muscle is in action. Under similar conditions the surface forms produced by the three heads of the muscle are well seen.

On the anterior aspect of the elbow are to be seen two muscular elevations, one on each side, separated above and converging below so as to form a triangular space. Of these, the inner elevation, consisting of the Flexors and Pronators, forms the prominence along the inner side and front of the forearm. It is a fusiform mass, pointed above at the internal condyle and gradually tapering off below. The **Pronator teres**, the innermost muscle of the group, forms the boundary of the triangular space at the bend of the elbow. It is shorter, less prominent, and more oblique than the outer boundary. The most prominent part of the eminence is produced by the **Flexor carpi radialis**, the muscle next in order on the inner side of the preceding one. It forms a rounded prominence above, and can be traced downward to its tendon, which can be felt lying on the front of the wrist, nearer to the radial than to the ulnar border, and to the inner side of the radial artery. The **Palmaris longus** presents no surface marking above, but below is the most prominent tendon on the front of the wrist, standing out, when the muscle is in action, as a sharp, tense cord beneath the skin. The **Flexor sublimis digitorum** does not directly influence surface form. The position of its four tendons on the front of the lower part of the forearm is indicated by an elongated depression between the tendons of the **Palmaris longus** and the **Flexor carpi ulnaris**. The **Flexor carpi ulnaris** occupies a small part of the posterior surface of the forearm, and is separated from the Extensor and Supinator group, which occupies the greater part of this surface, by the ulnar furrow, produced by the subcutaneous posterior border of the ulna. Its tendon can be perceived along the ulnar border of the front of the forearm, and is most marked when the hand is flexed and adducted. The deep muscles of the front of the forearm have no direct influence on surface form. The external group of muscles of the forearm, consisting of the Extensors and Supinators, occupy the outer and a considerable portion of the posterior surface of this region. It has a fusiform outline, which is altogether on a higher level than the Pronator teres and Flexors. Its apex emerges from between the Triceps and Brachialis anticus muscles some distance above the elbow-joint, and acquires its greatest breadth opposite the external condyle, and thence gradually shades off into a flattened surface. About the middle of the forearm it divides into two longitudinal eminences which diverge from each other, leaving a triangular interval between them. The outer of these two groups of muscles consists of the Brachioradialis and the Extensores carpi radialis longior et brevior, which form a longitudinal eminence descending from the external condylar ridge in the direction of the styloid process of the radius. The other and more posterior group consists of the Extensor communis digitorum, the Extensor minimi digiti, and the Extensor carpi ulnaris. It commences above as a tapering form at the external condyle of the humerus, and is separated behind at its upper part from the Anconeus by a well-marked furrow, and below, from the Pronator-flexor mass, by the ulnar furrow. In the triangular interval left between these two groups the Extensors of the thumb and index finger are seen. The only two muscles of this region which require special mention as independently influencing surface form are the Brachioradialis and the Anconeus. The inner border of the **Brachioradialis** forms the outer boundary of the triangular space at the bend of the elbow. It commences as a rounded border above the condyle, and is longer, less oblique, and more prominent than the inner boundary. Lower down, the muscle forms a full fleshy mass on the outer side of the upper part of the forearm, and below tapers into a tendon, which may be traced down to the styloid process of the radius. The **Anconeus** presents a well-marked and characteristic surface form in the shape of a triangular, slightly elevated surface, immediately external to the subcutaneous posterior surface of the olecranon, and differentiated from the common Extensor group by a well-marked oblique longitudinal depression. The upper angle of the triangle corresponds to the external condyle, and is marked by a depression or dimple in this situation. In the interval caused by the divergence from each other of the two groups of muscles into which the Extensor and Supinator group is divided at the lower part of the forearm an oblique elongated eminence is seen, caused by the emergence of two of the Extensors of the thumb from their deep origin at the back of the forearm. This eminence, full above and becoming flattened out and partially subdivided below, runs downward and outward over the back and outer surface of the radius to the outer side of the wrist-joint, where it forms a ridge, especially marked when the thumb is extended, which passes onward to the posterior aspect of the thumb. The tendons of most of the Extensor muscles are to be seen and felt at the level of the wrist-joint. Most externally are the tendons of the Extensor ossis metacarpi pollicis and the Extensor brevis pollicis, forming a vertical ridge over the outer side of the joint from the styloid process of the

radius to the thumb. Internal to this is the oblique ridge produced by the tendon of the Extensor longus pollicis, very noticeable when the muscle is in action. The Extensor carpi radialis longior is scarcely to be felt, but the Extensor carpi radialis brevis can be distinctly perceived as a vertical ridge emerging from under the inner border of the tendon of the Extensor longus pollicis, when the hand is forcibly extended at the wrist. Internal to this, again, can be felt the tendons of the Extensor indicis, Extensor communis digitorum, and Extensor minimi digiti; the latter tendon being separated from those of the common Extensor by a slight furrow.

The muscles of the hand are principally concerned, so far as regards surface form, in producing the **thenar** and **hypothenar eminences**, and individually are not to be distinguished, on the surface, from each other. The **Adductor transversus pollicis** is, however, an exception to this; its anterior border gives rise to a ridge across the web of skin connecting the thumb to the rest of the hand. The **thenar eminence** is much larger and rounder than the **hypothenar**, which presents a longer and narrower eminence along the ulnar side of the hand. When the **Palmaris brevis** is in action it produces a wrinkling of the skin over the hypothenar eminence, and a deep dimple on the ulnar border of the hand. The anterior extremities of the **Lumbrical muscles** help to produce the soft eminences just behind the clefts of the fingers, separated from each other by depressions corresponding to the Flexor tendons in their sheaths. Between the thenar and hypothenar eminences, at the wrist-joint, is a slight groove or depression, widening out as it approaches the fingers; beneath this we have the strong central part of the palmar fascia. On the back of the hand the **Dorsal interossei** produce elongated markings between the metacarpal bones. When the thumb is adducted the **First dorsal interosseous** forms a prominent fusiform bulging; the other Interossei are not so marked.

The skin over the inner side and front of the forearm is thin, smooth, and sensitive; it contains few hairs and many sweat glands. Over the outer side and back of the arm and forearm it is thicker, denser, and less sensitive, and contains more hairs and fewer sweat glands. Over the olecranon the cuticle is thick and rough; the skin is loosely connected to the underlying tissues and becomes transversely wrinkled when the forearm is extended. At the front of the wrist the skin presents three transverse furrows, which correspond from above downward to the position of the styloid process of the ulna, the wrist-joint, and the midcarpal joint, respectively. The skin of the palm of the hand differs considerably from that of the forearm. At the wrist it suddenly becomes hard and dense, and covered by a thick layer of cuticle. The skin in the thenar region presents these characteristics less than elsewhere. In spite of this hardness and density, the skin of the palm is exceedingly sensitive and very vascular. It is destitute of hair, and no sebaceous follicles have been found in this region. It is tied down by fibrous bands along the lines of flexion of the digits, producing certain furrows of a permanent character. One of these, starting from about the tubercle of the scaphoid, curves around the thenar eminence, and ends on the radial border of the hand, a little above the metacarpophalangeal joint of the index finger. It corresponds to the outer border of the central portion of the palmar fascia, and is produced by the movements of the thumb at the carpometacarpal joint. A second line begins at the end of the first and extends obliquely across the palm upward and inward, to the ulnar margin about the middle of the fifth metacarpal bone. A third commences at the ulnar border of the hand about an inch below the termination of the second and extends outward across the palm over the heads of the third, fourth, and fifth metacarpal bones. These last two lines are caused by the flexion of the fingers at the metacarpophalangeal joints. Over the fingers the skin again becomes thinner, especially at the flexures of the joints, and over the terminal phalanges it is thrown into numerous ridges in consequence of the arrangement of the papillae in it. These ridges form, in different individuals, distinctive and permanent patterns, which may be used for purposes of identification. The **superficial fascia** in the palm is made up of dense fibrofatty tissue. This tissue binds down the skin so firmly to the deep palmar fascia that very little movement is permitted between the two.

APPLIED ANATOMY OF THE UPPER EXTREMITY.

The student, having completed the dissection of the muscles of the upper extremity, should consider the effects likely to be produced by the action of the various muscles in fracture of the bones.

In considering the action of the various muscles upon fractures of the upper extremity, the most common forms of injury have been selected both for illustration and description.

Fracture of the *middle of the clavicle* (Fig. 372) is always attended with considerable displacement; the inner end of the outer fragment is displaced inward and backward, while the outer end of the same fragment is rotated forward. The whole outer fragment is somewhat depressed. The deformity is described by saying that the shoulder goes downward, forward, and inward.

The displacement is produced as follows: *inward*, by the muscles passing from the thorax to the outer fragment of the clavicle, to the scapula, and to the humerus—viz., the Subclavius and the Pectoralis minor, and, to a less extent, the Pectoralis major and the Latissimus dorsi; *backward*, in consequence of the rotation of the outer fragment. The Serratus magnus causes the scapula to rotate on the thoracic wall; this carries the acromion and outer end of the outer fragment of the clavicle forward and causes the piece of bone to rotate around a vertical axis through its centre, and so carries the inner end of the outer portion backward. The depression of the whole outer fragment is produced by the weight of the arm and by the contraction of the Deltoid. The outer end of the inner fragment appears to be elevated, the skin being drawn tensely over it; this is owing to the depression of the outer fragment, as the inner fragment is usually kept fixed by the costoclavicular ligament and by the antagonism between the Sternomastoid and Pectoralis major muscles. But it may be raised by an unusually strong Sternomastoid, or by the inner end of the outer fragment getting below and behind it. The causes of displacement having been ascertained, it is easy to apply the appropriate treatment. The outer fragment is to be drawn outward, and, together with the scapula, raised upward to a level with the inner fragment, and retained in that position. This deformity is corrected by carrying the shoulder upward, outward, and backward.

In fracture of the *acromial end of the clavicle*, between the conoid and trapezoid ligaments only slight displacement occurs, as these ligaments, from their oblique insertion, serve to hold both portions of the bone in apposition. Fracture, also, of the *sternal end*, internal to the costoclavicular ligament, is attended with only slight displacement, this ligament serving to retain the fragments in close apposition.

Fracture of the *acromion process* usually arises from violence applied to the upper and outer part of the shoulder; it is generally known by the rotundity of the shoulder being lost, from the Deltoid drawing the fractured portion downward and forward; and the displacement may easily be discovered by tracing the margin of the clavicle outward, when the fragment will be found resting on the front and upper part of the head of the humerus. In order to relax the anterior and outer fibres of the Deltoid (the opposing muscle), the arm should be drawn forward across the thorax and the elbow well raised, so that the head of the bone may press the acromion process upward and retain it in its position.

Fracture of the *coracoid process* is an extremely rare accident, and is usually caused by a sharp blow on the point of the shoulder. Displacement is here produced by the combined actions of the Pectoralis minor, the short head of the Biceps, and the Coracobrachialis, the former muscle drawing the fragment inward, and the latter muscles directly downward, the amount of displacement being limited by the connection of this process to the acromion by means of the coraco-acromial ligament. In many cases there appears to have been little or no displacement, from the fact that the coracoclavicular ligament has remained intact, and has kept the separated fragment from displacement. In order to relax these muscles and replace the fragments in close apposition, the forearm should be flexed so as to relax the Biceps, and the arm drawn forward and inward across the chest, so as to relax the Coracobrachialis; the humerus should then be pushed upward against the coraco-acromial ligament, and the arm retained in that position.

Fracture of the *surgical neck of the humerus* (Fig. 373) is very common, is attended with considerable displacement, and its appearances correspond somewhat with those of dislocation of the head of the humerus into the axilla. The upper fragment is slightly elevated under the coraco-acromial ligament by the muscles attached to the greater and lesser tuberosities; the lower fragment is drawn inward by the Pectoralis major, Latissimus dorsi, and Teres major; and the humerus is thrown obliquely outward from the side by the Deltoid, and occasionally elevated so as to cause the upper end of the lower fragment to project beneath and in front of the coracoid process. The deformity is reduced by fixing the shoulder, and drawing the arm outward and downward. To counteract the opposing muscles, and to keep the fragments in position, a conical-shaped pad should be placed with the apex in the axilla; while the forearm is flexed to an angle of 90 degrees the shoulder is padded with cotton, a shoulder-cap of plaster

FIG. 372.—Fracture of the middle of the clavicle.

of Paris is applied to cover the shoulder, a portion of the thorax and back, and the arm down to the external condyle (Scudder). The arm, with the elbow slightly forward, is bandaged to the side. In some cases a splint is placed between the axillary pad and the inner side of the arm.

In fracture of the *shaft of the humerus* below the insertion of the Pectoralis major, Latissimus dorsi, and Teres major, and above the insertion of the Deltoid, there is also considerable deformity, the upper fragment being drawn inward by the first-mentioned muscles, and the lower fragment upward and outward by the Deltoid, producing shortening of the limb and a considerable prominence at the seat of fracture, from the fractured ends of the bone riding over one another, especially if the fracture takes place in an oblique direction. The fragments may be brought into apposition by extension from the elbow, and are retained in that position by adopting the same means as in the preceding injury, or by the use of an internal angular splint with three short humeral splints.

FIG. 373.—Fracture of the surgical neck of the humerus.

In fractures of the *shaft of the humerus* immediately below the insertion of the Deltoid, the amount of deformity depends greatly upon the direction of the fracture. If it occurs in a transverse direction, only slight displacement takes place, the upper fragment being drawn a little forward; but in oblique fracture the combined actions of the Biceps and Brachialis anticus muscles in front and the Triceps behind draw upward the lower fragment, causing it to glide over the upper fragment, either backward or forward, according to the direction of the fracture. Simple extension reduces the deformity, and the application of an internal angular splint and three short humeral splints will retain the fragments in apposition. Care should be taken not to raise the elbow, but the forearm and hand may be supported in a sling.

Fracture of the *humerus* (Fig. 374) above the condyle deserves very attentive consideration, as the general appearances correspond somewhat with those produced by separation of the epiphysis of the humerus, and with those of dislocation of the radius and ulna backward. If the direction of the fracture is oblique from above, downward and forward, the lower fragment

FIG. 374.—Fracture of the humerus above the condyle.

FIG. 375.—Fracture of the olecranon.

is drawn upward by the Brachialis anticus and Biceps in front and the Triceps behind; and at the same time is drawn backward behind the upper fragment by the Triceps. This injury may be differentiated from dislocation by the increased mobility in fracture, the existence of crepitus, and the fact of the deformity being remedied by extension, on the discontinuance of which it is reproduced. The age of the patient is of importance in distinguishing this form of injury from separation of the epiphysis. If fracture occurs in the opposite direction to that

shown in Fig. 364, the lower fragment is drawn upward and forward, causing a considerable prominence in front, and the upper fragment projects backward beneath the tendon of the Triceps muscle.

Fracture of the *olecranon process* (Fig. 375) is a frequent accident. The detached fragment is displaced upward, by the action of the Triceps muscle, from half an inch to two inches; the prominence of the elbow is consequently lost, and a deep hollow is felt at the back part of the joint, which is much increased on flexing the limb. The patient at the same time loses, more or less, the power of extending the forearm. The treatment consists in relaxing the Triceps by extending the limb, and retaining it in the extended position by means of a long straight splint applied to the front of the arm; the fragments are thus brought into close apposition, and may be further approximated by drawing down the upper fragment. The fragments may be wired together and thus prevent the formation of a ligamentous union, as is generally the case when wiring is not employed; passive motion must be instituted at the end of the third week to prevent ankylosis.

Fracture of the *neck of the radius* is an exceedingly rare accident, and is generally caused by direct violence. Its diagnosis is somewhat obscure, on account of the slight deformity visible, the injured part being surrounded by a large number of muscles; but the movements of pronation and supination are entirely lost. The upper fragment is drawn outward by the Supinator [brevis], the extent of displacement being limited by the attachment of the orbicular ligament. The lower fragment is drawn forward and slightly upward by the Biceps, and inward by the Pronator teres, its displacement forward and upward being counteracted in some degree by the Supinator. The treatment essentially consists in relaxing the Biceps, Supinator, and Pronator teres muscles by flexing the forearm, and placing it in a position midway between pronation and supination, extension having been previously made so as to bring the parts in apposition.

FIG. 376.—Fracture of the shaft of the radius.

FIG. 377.—Fracture of the lower end of the radius.

In fracture of the *radius* below the insertion of the Biceps, but above the insertion of the Pronator teres, the upper fragment is strongly supinated by the Biceps and Supinator, and at the same time drawn forward and flexed by the Biceps; the lower fragment is pronated and drawn inward toward the ulna by the Pronators. Thus, there is extreme displacement with very little deformity. In treating such a fracture the arm must be put up in a position of supination, otherwise union will take place with great impairment of the movements of the hand. In fractures of the radius below the insertion of the Pronator teres (Fig. 376), the upper fragment is drawn upward by the Biceps and inward by the Pronator teres, holding a position midway between pronation and supination, and a degree of fullness in the upper half of the forearm is thus produced; the lower fragment is drawn downward and inward toward the ulna by the Pronator quadratus, and thrown into a state of pronation by the same muscle; at the same time, the Brachioradialis, by elevating the styloid process, into which it is inserted, will serve to depress the upper end of the lower fragment still more toward the ulna. In order to relax the opposing muscles the forearm should be bent, and the limb placed in a position midway between pronation and supination; the fracture is then easily reduced by extension from the wrist and elbow; well-padded splints should be applied on both sides of the forearm from the elbow to the wrist; the hand, being allowed to fall, will, by its own weight, counteract the action of the Pronator quadratus and of the Brachioradialis, and elevate the lower fragment to the level of the upper one.

In fracture of the *shaft of the ulna* the upper fragment retains its usual position, but the lower fragment is drawn outward toward the radius by the Pronator quadratus, producing a well-marked depression at the seat of fracture and some fulness on the dorsal and palmar surfaces of the forearm. The fracture is easily reduced by extension from the wrist and forearm. The forearm should be flexed, and placed in a position midway between pronation and supination, and well-padded splints applied from the elbow to the ends of the fingers.

In fracture of the *shafts of the radius and ulna together* the lower fragments are drawn upward, sometimes forward, sometimes backward, according to the direction of the fracture, by the combined actions of the Flexor and Extensor muscles, producing a degree of fulness on the dorsal or palmar surface of the forearm; at the same time the two fragments are drawn into contact by the Pronator quadratus, the radius being in a state of pronation; the upper fragment of the radius is drawn upward and inward by the Biceps and Pronator teres to a higher level than the ulna; the upper portion of the ulna is slightly elevated by the Brachialis anticus. The fracture may be reduced by extension from the wrist and elbow, and the forearm should be placed in the same position as in fracture of the ulna.

In fracture of the *lower end of the radius (Colles' fracture)* (Fig. 377) the displacement which is produced is very considerable, and bears some resemblance to dislocation of the carpus backward, from which it should be carefully distinguished. The lower fragment is displaced backward and upward, but this displacement is probably due to the force of the blow driving the portion of the bone into this position and not to any muscular influence. The upper fragment projects forward, often lacerating the substance of the Pronator quadratus, and is drawn by this muscle into close contact with the lower end of the ulna, causing a projection on the anterior surface of the forearm, immediately above the carpus, from the Flexor tendons being thrust forward. This fracture may be distinguished from dislocation by the deformity being removed on making sufficient extension, when crepitus may be occasionally detected; at the same time, on extension being discontinued, the parts immediately resume their deformed appearance. The age of the patient will also assist in determining whether the injury is fracture or separation of the epiphysis. Reduction is effected by hyperextension, longitudinal traction, and forced flexion.¹ The posterior straight splint with suitable pads is the best dressing.

MUSCLES AND FASCIÆ OF THE LOWER EXTREMITY.

The muscles of the lower extremity are subdivided into groups corresponding with the different regions of the limb.

I. ILIAC REGION.

Psoas magnus.
Psoas parvus.
Iliacus.

2. Internal Femoral Region.

Interossei.

I. MUSCLES AND FASCIÆ OF THE ILIAC REGION.

Psoas magnus.

Psoas parvus.

Iliacus.

Dissection.—No detailed description is required for the dissection of these muscles. On the removal of the viscera from the abdomen they are exposed, covered by the peritoneum and a thin layer of fascia, the iliac fascia.

The **iliac fascia** (*fascia iliaca*) is the aponeurotic layer which lines the back part of the abdominal cavity, and covers the Psoas and Iliacus muscles throughout their whole extent. It is thin above, and becomes gradually thicker below as it approaches the femoral arch.

The portion covering the Psoas is thickened, above, to form the *ligamentum arcuatum internum*; internally it is attached, by a series of arched processes, to the intervertebral substances, to the prominent margins of the bodies of the vertebræ, and to the upper part of the sacrum, the intervals so left, opposite the constricted portions of the bodies, transmitting the lumbar arteries and veins and the filaments of the sympathetic cord. Externally, above the crest of the ilium, this portion of the iliac fascia is continuous with the anterior lamella of the lumbar fascia covering the front of the Quadratus lumborum, but below the crest of the ilium it is continuous with the fascia covering the Iliacus.

The portion investing the **Iliacus** is connected externally to the whole length of the inner border of the crest of the ilium, and internally to the brim of the true pelvis, where it is continuous with the periosteum; at the iliopectineal eminence it receives the tendon of insertion of the **Psoas parvus**, when that muscle exists. External to the external iliac vessels, this fascia is intimately connected to the posterior margin of **Poupart's ligament**, and is continuous with the **fascia transversalis**. Immediately to the outer side of the external iliac vessels, as they pass beneath **Poupart's ligament**, the **fascia iliaca** is prolonged backward and inward from **Poupart's ligament** as a band, the **iliopectineal ligament**, and is attached to the iliopectineal eminence. The ligament divides the space between

FIG. 378.—Poupart's ligament and the relation of the parts passing beneath it. (Poirier and Charpy.)

Poupart's ligament and the horizontal ramus of the pubis into two parts, the inner of which (*lacuna vasorum*) transmits the femoral vessels, is bounded internally by the base of **Gimbernath's ligament** and contains the femoral ring. The outer part (*lacuna musculorum*) transmits the **Iliopsoas** and the femoral nerve (Fig. 378). Internal to the vessels the **iliac fascia** is attached to the iliopectineal line behind the conjoined tendon, where it is again continuous with the **transversalis fascia**; and, corresponding to the point where the femoral vessels pass into the thigh, this fascia descends behind them, forming the posterior wall of the femoral sheath. This portion of the **iliac fascia** which passes behind the femoral vessels is also attached to the iliopectineal line beyond the limits of the attachment of the conjoined tendon; at this part it is continuous with the pubic portion of the **fascia lata** of the thigh. The external iliac ves-

sels lie in front of the **iliac fascia**, but all the branches of the lumbar plexus lie behind it; it is separated from the peritoneum by a quantity of loose areolar tissue. The **femoral sheath** (*fascia cruris*) is formed by the **transversalis fascia** in front of the vessels and the **iliac fascia** behind them. The fasciæ join to the inner side of the femoral vein, a space, the **femoral canal**, intervening between the vein and their junction.

Between the femoral vein and the edge of **Gimbernath's ligament** is the **femoral or crural ring** (*annulus femoralis*) (Fig. 380). The **femoral canal** (*canalis femoralis*) is the interval between the femoral vein and the inner wall of the femoral sheath. This canal extends from the femoral ring to the saphenous opening. The femoral ring is closed by the **septum crurale of Cloquet** (*septum femorale* [Cloqueti]), which is a process of **transversalis fascia**.

The **Psoas magnus** (*m. psoas major*) (Fig. 381) is a long fusiform muscle placed on the side of the lumbar region of the vertebral column and the margin of the pelvis. It *arises* from the front of the bases and lower borders of the transverse processes of the lumbar vertebræ by five fleshy slips; also from the sides of the bodies and the corresponding intervertebral substances of the last thoracic and all the lumbar vertebræ. The muscle is connected to the bodies of the vertebræ by five slips; each slip is attached to the upper and lower margins of two vertebræ, and to the intervertebral substance between them, the slips themselves being connected by the tendinous arches which extend across the constricted part of the bodies, and beneath which pass the lumbar arteries and veins and filaments of the sympathetic cord. These tendinous arches also give origin to muscle fibres, and protect the bloodvessels and nerves from pressure during the action of the muscle. The first slip is attached to the contiguous margins of the last thoracic and first lumbar vertebræ; the last to the contiguous margins of the fourth and fifth lumbar vertebræ, and to the intervertebral substance. From these points the muscle descends across the brim of the pelvis, and, diminishing gradually in size, passes beneath Poupart's ligament, and terminates in a tendon which, after receiving nearly the whole of the fibres of the Iliacus, is *inserted* into the lesser trochanter of the femur.

Relations.—In the lumbar region, by its *anterior surface*, which is placed behind the peritoneum, the Psoas magnus is in relation with the fascia which covers it, with the ligamentum arcuatum internum, the kidney, Psoas parvus, renal vessels, ureter, spermatic vessels, genito-femoral nerve, and the colon. In many cases the vermiform appendix rests upon the right Psoas muscle (page 506). By its *posterior surface*, with the transverse processes of the lumbar vertebræ and the Quadratus lumborum muscle, from which it is separated by the anterior lamella of the lumbar fascia. The lumbar plexus is situated in the posterior part of the substance of the muscle. By its *inner side* the muscle is in relation with the bodies of the lumbar vertebræ, the lumbar arteries, the ganglia of the sympathetic cord, and their branches of communication with the spinal nerves; the lumbar nodes; the inferior vena cava on the right and the aorta on the left side, and along the brim of the pelvis with the external iliac artery. In the *thigh* it is in relation, *superficially*, with the fascia lata; *deeply*, with the capsular ligament of the hip, from which it is separated by a synovial bursa (*bursa iliopectinea*), which frequently communicates with the cavity of the joint through an opening of variable size; between the tendon and part of the lesser trochanter is the *bursa iliaca subtendinea*; by its *inner border*, with the Pectineus and internal circumflex artery, and also with the femoral artery, which slightly overlaps it; by its *outer border*, with the femoral nerve and Iliacus muscle.

The **Psoas parvus** (*m. psoas minor*) (Fig. 381) is a long, slender muscle placed in front of the Psoas magnus. It *arises* from the sides of the bodies of the last thoracic and first lumbar vertebræ and from the intervertebral substance between them. It forms a small, flat, fleshy bundle, which terminates in a long flat tendon *inserted* into the iliopectineal eminence, and, by its outer border, into the iliac fascia. This muscle is often absent, and is sometimes double.

The **Iliacus** (*m. iliacus*) (Fig. 381) is a flat, triangular muscle which fills up the whole of the iliac fossa. It *arises* from the upper two-thirds of this fossa and from the inner margin of the crest of the ilium; *behind*, from the iliolumbar ligament and base of the sacrum; in *front*, from the anterior superior and anterior inferior spinous processes of the ilium, from the notch between them. The fibres converge to be *inserted* into the outer side of the tendon of the Psoas, some of them being prolonged and attached to the shaft of the femur for about an inch below and in front of the lesser trochanter.¹ The most external fibres are inserted into the capsule of the hip-joint.

Relations.—Within the *abdomen*, by its *anterior surface*, with the iliac fossa, which separates the muscle from the peritoneum, and with the external cutaneous nerve; on the right side, with the cecum; on the left side, with the pelvic colon; by its *posterior surface*, with the iliac fossa; by its *inner border*, with the Psoas magnus and femoral nerve. In the *thigh*, it is in

¹ The Psoas and Iliacus are often regarded as a single muscle—the Iliopsoas—having two heads of origin and a single insertion.

relation, by its *superficial surface*, with the fascia lata, the Rectus and Sartorius muscles, and the profunda femoris artery; by its *deep surface*, with the capsule of the hip-joint, a synovial bursa common to it and the Psoas magnus being interposed.

Nerves.—The Psoas magnus is supplied by the anterior branches of the second and third lumbar nerves; the Psoas parvus, when it exists, is supplied by the anterior branch of the first lumbar nerve; and the Iliacus, by the anterior branches of the second and third lumbar nerves through the femoral.

Actions.—The Psoas and Iliacus muscles, acting from above, flex the thigh upon the pelvis. Acting from below, the femur being fixed, the muscles of both sides bend the lumbar portion of the vertebral column and pelvis forward. They also serve to maintain the erect position, by supporting the vertebral column and pelvis upon the femur, and assist in raising the trunk when the body is in the recumbent posture.

The Psoas parvus is a tensor of the iliac fascia. It assists in flexing the lumbar portion of the vertebral column laterally, the pelvis being its fixed point.

Applied Anatomy.—There is no definite septum between the portions of the iliac fascia covering the Psoas and Iliacus, respectively, and the fascia is only connected to the subjacent muscles by a quantity of loose connective tissue. When an *abscess* forms beneath this fascia, as it is very liable to do, the pus is contained in an osseofibrous cavity, which is closed on all sides within the abdomen, and is open only at its lower part, where the fascia is prolonged over the muscle into the thigh.

Abscess within the sheath of the Psoas muscle (*Psoas abscess*) is generally due to tuberculous caries of the bodies of the lower thoracic or of the lumbar vertebræ. When the disease is in the thoracic region, the pus courses down the posterior mediastinum, in front of the bodies of the vertebræ, and, passing beneath the ligamentum arcuatum internum, enters the sheath of the Psoas muscle, down which it passes as far as the pelvic brim; it then gets beneath the iliac portion of the fascia and fills up the iliac fossa. In consequence of the attachment of the fascia to the pelvic brim, it rarely finds its way into the pelvis, but passes by a narrow opening under Poupart's ligament into the thigh, to the outer side of the femoral vessels. It thus follows that a Psoas abscess may be described as consisting of four parts: (1) A somewhat narrow channel at its upper part, in the Psoas sheath; (2) a dilated sac in the iliac fossa; (3) a constricted neck under Poupart's ligament; and (4) a dilated sac in the upper part of the thigh. When the lumbar vertebræ are the seat of the disease, the pus finds its way directly into the substance of the muscle. If a Psoas abscess forms, the muscle fibres are destroyed, and the nerve cords contained in the abscess are isolated and exposed in its interior; the femoral vessels which lie in front of the fascia remain intact, and the peritoneum seldom becomes implicated. All Psoas abscesses do not, however, pursue this course; the pus may leave the muscle above the crest of the ilium, and, tracking backward, may point in the loin (*lumbar abscess*); or it may point above Poupart's ligament in the inguinal region; or it may follow the course of the iliac vessels into the pelvis, and, passing through the great sacrosciatic notch, discharge itself on the back of the thigh; it may open into the bladder or find its way into the perineum, or it may pass down the thigh to the popliteal space or even lower. *Strain* of the Psoas muscle is not unusual, and induces pain which may be mistaken for appendicitis. The *bursa* beneath the tendon of the Psoas and Iliacus and the hip-joint or that between the tendon and the lesser trochanter may greatly enlarge and produce pain and disablement. Byron Robinson¹ pointed out that trauma of the Psoas muscle may be an important factor in the etiology of appendicitis, as it may induce periappendicular adhesions which interfere with the circulation of blood and feces. Robinson says, in the previously quoted article, that in 46 per cent. of men and in 20 per cent. of women the appendix rests on the Psoas muscle.

Dissection.—To expose the muscles and fasciæ in this region, make an incision along Poupart's ligament, from the anterior superior spine of the ilium to the spine of the os pubis;

¹ Annals of Surgery, April, 1901.

a vertical incision from the centre of this, along the middle of the thigh to below the knee-joint; and a transverse incision from the inner to the outer side of the leg, at the lower end of the vertical incision. The flaps of integument having been removed, the superficial and deep fasciæ should be examined. The more advanced student should commence the study of this region by an examination of the anatomy of femoral hernia and Scarpa's triangle, the incisions for the dissection of which are marked out in Fig. 379.

Superficial Fascia.—The superficial fascia forms a continuous layer over the whole of the thigh. It consists of areolar tissue, containing in its meshes much fat, and is capable of being separated into two or more layers, between which are found the superficial vessels and nerves. It varies in thickness in different parts of the limb; in the groin it is thick, and the two layers are separated from one another by the superficial inguinal lymph nodes, the internal saphenous vein, and several smaller vessels. One of these two layers, the superficial, is continuous above with the superficial fascia of the abdomen. Internally it is continuous with the superficial fascia of the perineum. The deep layer of the superficial fascia is a very thin fibrous layer, best marked on the inner side of the long saphenous vein and below Poupart's ligament. It is placed beneath the subcutaneous vessels and nerves and upon the surface of the fascia lata. It is intimately adherent to the fascia lata a little below Poupart's ligament. It covers the saphenous opening (Fig. 380) in the fascia lata, being closely united to the margins of the opening, and is connected to the sheath of the femoral vessels. The portion of the fascia covering this aperture is perforated by the internal saphenous vein and by numerous bloodvessels and lymphatic vessels; hence, it has been termed the **cribriform fascia** (*fascia cribrosa*). The cribriform fascia adheres closely both to the superficial fascia and to the fascia lata, so that it is described by some anatomists as part of the fascia lata, but is usually considered (as in this work) as belonging to the superficial fascia. It is not until the cribriform fascia has been cleared away that the saphenous opening is seen, so that this opening does not in ordinary cases exist naturally, but is the result of dissection. A large subcutaneous bursa (*bursa præpatellaris subcutanea*) is found in the superficial fascia over the patella, and another (*bursa trochanterica subcutanea*) in the superficial fascia over the great trochanter.

The Deep Fascia, or Fascia Lata (Fig. 380).—The deep fascia of the thigh is exposed on the removal of the superficial fascia, and is named, from its great extent, the **fascia lata**; it forms a uniform investment for the whole of this region of the limb, but varies in thickness in different parts; thus, it is thicker in the upper and outer part of the thigh, where it receives a fibrous expansion from the Gluteus maximus muscle, and where the Tensor fasciæ femoris is inserted between its layers; it is very thin behind, and at the upper and inner part where it covers the Adductor muscles, and again becomes stronger around the knee, receiving

FIG. 379.—Dissection of lower extremity. Front view.

fibrous expansions from the tendons of the Biceps femoris externally, from the Sartorius internally, and from the Quadriceps extensor in front. The fascia lata is attached *above*, and *behind*, to the back of the sacrum and coccyx; *externally*, to the crest of the ilium; in *front*, to Poupart's ligament and to the body of the os pubis; and *internally*, to the descending ramus of the os pubis, to the ramus and tuberosity of the ischium, and to the lower border of the great sacrosciatic ligament. From its attachment to the crest of the ilium it passes down over the Gluteus medius muscle to the upper border of the Gluteus maximus, where it splits into two layers, one passing superficial to and the other beneath this muscle. At the lower border of the muscle the two layers reunite. Externally the fascia lata receives the greater part of the tendon of insertion of the Gluteus maximus, and becomes proportionately thickened. The portion of the fascia lata arising from the front part of the crest of the ilium, corresponding to the origin of the Tensor

FIG. 380.—Right external abdominal ring and saphenous opening in the male. (Spalteholz.)

fasciæ femoris, passes down the outer side of the thigh as two layers, one superficial to and the other beneath this muscle. These layers at the lower end of the muscle become blended into a thick and strong band, having first received the insertion of the muscle. This band is continued downward, under the name of the **iliotibial band** (*tractus iliotibialis* [Maissiat]), to be inserted into the external tuberosity of the tibia. Below, the fascia lata is attached to all the prominent points around the knee-joint—viz., the condyles of the femur, tuberosities of the tibia, and head of the fibula. On each side of the patella it is strengthened by transverse fibres given off from the lower part of the Vasti muscles, which are attached to and support this bone. Of these, the outer fibres are the stronger, and are continuous with the iliotibial band. From the deep surface of the fascia lata are given off two strong **intermuscular septa**, which are attached to the whole length of the linea aspera and its prolongations above and below; the **external**

intermuscular septum (*septum intermusculare laterale*) is the stronger. It extends from the insertion of the Gluteus maximus to the outer condyle, separates the Vastus externus in front from the short head of the Biceps femoris behind, and gives partial origin to these muscles; the **internal intermuscular septum** (*septum intermusculare mediale*), the thinner of the two, separates the Vastus internus from the Adductor and Pectineus muscles. Besides these there are numerous smaller septa, separating the individual muscles and enclosing each in a distinct sheath. At the upper and inner part of the thigh, a little below Poupart's ligament, a large, oval-shaped aperture is observed; it transmits the internal saphenous vein and other smaller vessels, and is termed the **saphenous opening** (*fossa ovalis*) (Fig. 380). This opening is covered by a portion of the deep layer of the superficial fascia, the **cribriform fascia**. In order more correctly to consider the mode of formation of this aperture, the fascia lata in this part of the thigh is described as consisting of two portions—an iliac portion and a pubic portion.

The **iliac portion** is all that part of the fascia lata on the outer side of the saphenous opening. It is attached, *externally*, to the crest of the ilium and its anterior superior spine, to the whole length of Poupart's ligament as far internally as the spine of the os pubis, and to the iliopectineal line in conjunction with Gimbernat's ligament. From the spine of the os pubis it is reflected downward and outward, forming an arched margin, the **falciform process** or the **falciform margin of Burns** (*margo falciformis*). This margin overlies and is adherent to the superficial layer of the sheath of the femoral vessels; to its edge is attached the cribriform fascia; and, *below*, it is continuous with the pubic portion of the fascia lata. The **femoral ligament**, or the **ligament of Hey**, is the point at which the falciform process joins the base of Gimbernat's ligament.

The **pubic portion** is situated at the inner side of the saphenous opening; at the lower margin of this aperture it is continuous with the iliac portion. Traced upward, the pubic portion covers the surface of the Pectineus, Adductor longus, and Gracilis muscles, and, passing behind the sheath of the femoral vessels, to which it is closely united, is continuous with the sheath of the Psoas and Iliacus muscles, and is attached above to the iliopectineal line, where it becomes continuous with the iliac fascia. From this description it may be observed that the iliac portion of the fascia lata passes superficial to the femoral vessels, and the pubic portion behind them, so that an apparent aperture exists between the two, through which the internal saphenous joins the femoral vein.

Applied Anatomy.—The *iliotibial band* at a point between the crest of the ilium and the great trochanter is so tense that it is impossible to sink the fingers deeply in this region. Dr. Allis points out that in fracture of the neck of the femur the great trochanter mounts toward the iliac crest, the iliotibial band relaxes, and the fingers can be sunk deeply into the space between the great trochanter and the iliac crest. Shortening is thus indicated. This is known as *Allis' sign*. A *Psoas abscess* usually points at the termination of the Psoas muscle, but the tuberculous pus may be directed down the thigh beneath the fascia lata, and it may reach the popliteal space or may go even lower.

The **Tensor fasciæ femoris** (*m. tensor fasciæ latae*) (Fig. 381) *arises* from the anterior part of the outer lip of the crest of the ilium, from the outer surface of the anterior superior spine, and part of the outer border of the notch below it, between the Gluteus medius and Sartorius, and from the surface of the fascia covering the Gluteus medius. It is *inserted* between two layers of the fascia lata, about one-fourth down the outer side of the thigh. From the point of insertion the fascia is continued downward to the external tuberosity of the tibia as a thickened band, the **iliotibial band**.

The **Sartorius** (*m. sartorius*) (Fig. 381), the longest muscle in the body, is flat, narrow, and ribbon-like; it *arises* by tendinous fibres from the anterior superior

FIG. 381.—Muscles of the iliac and anterior femoral region.

spine of the ilium and the upper half of the notch below it, passes obliquely across the upper and anterior part of the thigh, from the outer to the inner side of the limb, then descends vertically, as far as the inner side of the knee, passing behind the inner condyle of the femur, and terminates in a tendon which, curving obliquely forward, expands into a broad aponeurosis, to be inserted in front of the Gracilis and Semitendinosus, into the upper part of the inner surface of the shaft of the tibia, nearly as far forward as the crest. The upper part of the tendon is curved backward over the upper edge of the tendon of the Gracilis in order to be inserted behind it. An offset is derived from the upper margin of this aponeurosis, which blends with the fibrous capsule of the knee-joint, and another, given off from its lower border, blends with the fascia on the inner side of the leg.

Relations.—By its *superficial surface*, with the fascia lata; by its *deep surface*, with the Rectus femoris, Iliacus, Vastus internus, femoral nerve, sheath of the femoral vessels, Adductor longus, Gracilis, Semitendinosus, long saphenous nerve, and internal lateral ligament of the knee-joint. Frequently there is a *bursa* (*bursa m. sartorii propria*) between the tendon of the Sartorius and the tendons of the Gracilis and Semimembranosus.

The relations of this muscle to the femoral artery should be carefully examined, as it constitutes the chief guide in tying the vessel. In the upper third of the thigh it forms the outer side of a triangular space, **Scarpa's triangle** (*trigonum femorale*), the inner side of which is formed by the inner border of the Adductor longus, and the base, which is turned upward, by Poupart's ligament; the femoral artery passes perpendicularly through the middle of this space from its base to its apex. In the middle third of the thigh the femoral artery lies first along the inner border, and then behind the Sartorius.

The **Quadriceps extensor** (*m. quadriceps femoris*) (Fig. 381) includes the four remaining muscles on the front of the thigh. It is the great Extensor muscle of the leg, forming a large fleshy mass which covers the front and sides of the femur, being united below into a single tendon, attached to the patella, and above subdivided into separate portions, which have received distinct names. Of these, one occupying the middle of the thigh, connected above with the ilium, is called the **Rectus femoris**, from its straight course. The other divisions lie in immediate connection with the shaft of the femur, which they cover from the trochanters to the condyles. The

portion on the outer side of the femur is termed the **Vastus externus**; that covering the inner side, the **Vastus internus**; and that covering the front of the femur, the **Crureus**.

The **Rectus femoris** (*m. rectus femoris*) is situated in the middle of the anterior region of the thigh; it is fusiform in shape, and its superficial fibres are arranged in a bipenniform manner, the deep fibres running straight down to the deep aponeurosis. It *arises* by two tendons—one, the anterior or straight, from the anterior inferior spine of the ilium; the other, the posterior or reflected tendon, from a groove above the brim of the acetabulum; the two unite at an acute angle and spread

FIG. 382.—Diagram showing the attachments of the muscles of the thigh. Anterior aspect. Origins, red; insertions, blue.

into an aponeurosis, which is prolonged downward on the anterior surface of the muscle and from which the muscle fibres arise.¹ The muscle terminates in a broad and thick aponeurosis, which occupies the lower two-thirds of its posterior surface, and, gradually becoming narrowed into a flattened tendon, is *inserted* into the patella in common with the Vasti and Crureus. Between the tendon of origin and the acetabulum there is often a **bursa** (*bursa m. recti femoris*).

¹ Mr. W. R. Williams, in an interesting paper in the *Journ. of Anat. and Phys.*, vol. xiii, p. 204, points out that the reflected tendon is the real origin of the muscle, and is alone present in early fetal life. The direct tendon is merely an accessory band of condensed fascia. The paper will well repay perusal, though in some particulars the description in the text is more generally accurate.

The **Vastus externus** (*m. vastus lateralis*) is the largest division of the Quadriceps extensor. It arises by a broad aponeurosis, which is attached to the upper half of the anterior intertrochanteric line, to the anterior and inferior borders of the root of the great trochanter, to the outer lip of the gluteal ridge, and to the upper half of the outer lip of the linea aspera; this aponeurosis covers the upper three-fourths of the muscle, and from its inner surface many fibres take origin. A few additional fibres arise from the tendon of the Gluteus maximus, and from the external intermuscular septum between the Vastus externus and short head of the Biceps. The fibres form a large fleshy mass, which is attached to a strong aponeurosis, placed on the under surface of the muscle at its lower part; this becomes

FIG. 383.—Transverse section of the thigh below the trochanter minor. The femoral artery, vein, and nerve are seen in Hunter's canal. (After Braune.)

narrowed and thickened into a flat tendon, which is *inserted* into the outer border of the patella, blending with the Quadriceps extensor tendon, and giving an expansion to the capsule of the knee-joint. Some of the fibres run down by the side of the patella to the condyle of the tibia, and are called the **retinaculum patellae laterale**.

The **Vastus internus** and **Crureus** appear to be inseparably united, but when the Rectus femoris has been reflected, a narrow interval will be observed extending upward from the inner border of the patella between the two muscles. Here they can be separated, and the separation should be continued upward as far as the lower part of the anterior intertrochanteric line, where, however, the two muscles are frequently continuous.

The **Vastus internus** (*m. vastus medialis*) arises from the lower half of the anterior intertrochanteric line, the spiral line, the inner lip of the linea aspera, the upper part of the internal supracondylar line, the tendon of the Adductor magnus, and

the internal intermuscular septum. Its fibres are directed downward and forward, and are chiefly attached to an aponeurosis which lies on the deep surface of the muscle and is *inserted* into the inner border of the patella and the Quadriceps extensor tendon, an expansion being sent to the capsule of the knee-joint. Some of the fibres run down by the side of the patella to the condyle of the tibia and are called the **retinaculum patellae mediale**.

The **Crureus** (*m. vastus intermedius*) arises from the front and outer aspect of the shaft of the femur in its upper two-thirds and from the lower part of the external intermuscular septum. Its fibres end in a superficial aponeurosis, which forms the deep part of the Quadriceps extensor tendon.

FIG. 384.—Transverse section at the middle of the leg. In front of the interosseous membrane are the anterior tibial vessels and nerve; in front of the Soleus, the posterior tibial vessels and nerve; and close to the fibula, the peroneal vessels. (After Braune.)

Relations.—The *inner edge* of the Crureus is in contact with the anterior edge of the Vastus internus, but when separated from each other, as directed above, the latter muscle is seen merely to overlap the inner aspect of the femoral shaft without taking any fibres of origin from it. The Vastus internus is partly covered by the Rectus femoris and Sartorius, but where these separate near the knee it becomes superficial, and produces a well-marked prominence above the inner aspect of the knee. In the middle third of the thigh it forms the *outer wall* of **Hunter's canal** (*canalis adductorius* [Hunteri]) (Fig. 383), which contains the femoral vessels and the long saphenous nerve; the *roof* of the canal is formed by a strong fascia which extends from the Vastus internus to the Adductores longus and magnus. The Crureus is almost completely hidden by the Rectus femoris and Vastus externus. The *deep surface* of the two muscles is in relation with the femur and Subcrureus muscles. A synovial **bursa** (*bursa suprapatellaris*) is situated between the femur and the portion of the Quadriceps extensor tendon above the patella; in the adult it communicates with the synovial cavity of the knee-joint.

The **tendons** of the different portions of the Quadriceps extensor unite at the lower part of the thigh, so as to form a single strong tendon, which is *inserted* into the upper part of the patella; some few fibres pass over it to blend with the ligamentum patellae. Strictly speaking, the patella may be regarded as a sesamoid bone, developed in the tendon of the Quadriceps; and

the ligamentum patellæ, which is continued from the lower part of the patella to the tuberosity of the tibia, as the proper tendon of insertion of the muscle. A synovial bursa, the **deep patellar bursa** (*bursa infrapatellaris profunda*), is interposed between the tendon and the upper part of the tuberosity of the tibia; and another, the **prepatellar bursa** (*bursa præpatellaris subcutanea*), is placed over the patella itself. This latter bursa often becomes enlarged, constituting "housemaid's knee."

The **Subcrureus** (*m. articularis genu*) is a small muscle, usually distinct from the Crureus, but occasionally blended with it, which *arises* from the anterior surface of the lower part of the shaft of the femur, and is *inserted* into the upper part of the *cul-de-sac* of the capsular ligament, which projects upward beneath the Quadriceps for a variable distance. It sometimes consists of several separate muscle bundles.

Nerves.—The Tensor fasciæ femoris is supplied by the fourth and fifth lumbar and first sacral nerves through the superior gluteal nerve; the other muscles of this region, by the second, third, and fourth lumbar nerves, through branches of the femoral.

Actions.—The Tensor fasciæ femoris is a tensor of the fascia lata; continuing its action, the oblique direction of its fibres enables it to abduct and to rotate the thigh inward. In the erect posture, acting from below, it will serve to steady the pelvis upon the head of the femur, and by means of the iliotibial band it steadies the condyles of the femur on the articular surfaces of the tibia, and assists the Gluteus maximus in supporting the knee in the extended position. The Sartorius flexes the leg upon the thigh, and, continuing to act, flexes the thigh upon the pelvis; it next rotates the thigh outward. It was formerly supposed to adduct the thigh, so as to cross one leg over the other, and hence received its name of Sartorius, or tailor's muscle, because it was supposed to assist in crossing the legs in the squatting position. When the knee is bent the Sartorius assists the Semitendinosus, Semimembranosus, and Popliteus in rotating the tibia inward. Taking its fixed point from the leg, it flexes the pelvis upon the thigh, and, if one muscle acts, assists in rotating the pelvis. The Quadriceps extensor extends the leg upon the thigh. The Rectus muscle assists the Psoas and Iliacus in supporting the pelvis and trunk upon the femur. It also assists in flexing the thigh on the pelvis, or if the thigh is fixed it will flex the pelvis. The Vastus internus draws the patella inward as well as upward.

Applied Anatomy.—A few fibres of the Rectus femoris muscle are liable to be ruptured from severe strain. This accident is especially liable to occur during the games of football and baseball. The patient experiences a sudden pain in the part, as if he had been struck, and the Rectus muscle stands out and is felt to be tense and rigid. The accident is often followed by considerable swelling from inflammatory effusion. Occasionally the Quadriceps extensor may be torn away from its insertion into the patella, or the tendon of the Quadriceps may be ruptured about an inch above the bone. This accident is caused in the same manner that fracture of the patella by muscular action is produced—viz., by a violent muscular effort to prevent falling while the knee is in a position of semiflexion. A distinct gap can be felt above the patella, and, owing to the retraction of the muscle fibres, union may fail to take place. Sudden and powerful contraction of the Quadriceps extensor femoris is the usual cause of transverse fracture of the patella.

2. The Internal Femoral Region.

Gracilis.

Pectineus.

Adductor longus.

Adductor brevis.

Adductor magnus.

Dissection.—These muscles are at once exposed by removing the fascia from the fore part and inner side of the thigh. The limb should be abducted, so as to render the muscles tense and easier of dissection.

The **Gracilis** (*m. gracilis*) (Figs. 381 and 387) is the most superficial muscle on the inner side of the thigh. It is thin and flattened, broad above, narrowing and tapering below. It *arises* by a thin aponeurosis from the lower half of the margin of the symphysis and the anterior half of the pubic arch. The fibres pass vertically downward, and terminate in a rounded tendon which passes behind the internal condyle of the femur, and, curving around the inner tuberosity of the tibia,

becomes flattened, and is *inserted* into the upper part of the inner surface of the shaft of the tibia, below the tuberosity. A few of the fibres of the lower part of the tendon are prolonged into the deep fascia of the leg. The tendon of this muscle is situated immediately above that of the Semitendinosus, and its upper edge is overlapped by the tendon of the Sartorius, with which it is in part blended. As it passes across the internal lateral ligament of the knee-joint it is separated from it by a *synovial bursa* (*bursa anserina*) common to it and the Semitendinosus muscle.

Relations.—By its *superficial surface*, with the fascia lata and the Sartorius below; the internal saphenous vein crosses it obliquely near its lower part, lying superficial to the fascia lata; the internal saphenous nerve emerges between its tendon and that of the Sartorius; by its *deep surface*, with the Adductor brevis and the Adductor magnus and the internal lateral ligament of the knee-joint.

The Pectineus (*m. pectineus*) (Fig. 381) is a flat, quadrangular muscle, situated at the anterior part of the upper and inner aspect of the thigh. It *arises* from the iliopectineal line, and to a slight extent from the surface of the bone in front of it between the pectineal eminence and spine of the os pubis, and from the fascia covering the anterior surface of the muscle; the fibres pass downward, backward, and outward, to be *inserted* into a rough line leading from the lesser trochanter to the linea aspera.

Relations.—By its *superficial surface*, with the pubic portion of the fascia lata, which separates it from the femoral vessels and internal saphenous vein; by its *deep surface*, with the capsular ligament of the hip-joint, the Adductor brevis and Obturator externus muscles, the obturator vessels and nerve being interposed; by its *outer border*, with the Psoas, a cellular interval separating them, through which pass the internal circumflex vessels; by its *inner border*, with the margin of the Adductor longus. There is usually a *bursa* (*bursa m. pectinei*) between the Pectineus and the tendon of the Psoas and Iliacus.

The Adductor longus (*m. adductor longus*) (Figs. 381 and 385), the most superficial of the three Adductors, is a flat triangular muscle lying on the same plane as the Pectineus. It *arises*, by a flat narrow tendon, from the front of the os pubis, at the angle of junction of the crest with the symphysis; and soon expands into a broad fleshy belly, which, passing downward, backward, and outward, is *inserted*, by an aponeurosis, into the linea aspera,

FIG. 385.—Deep muscles of the internal femoral region.

between the Vastus internus and the Adductor magnus, with both of which it is usually blended.

Relations.—By its *superficial surface*, with the fascia lata, the Sartorius, and, near its insertion, with the femoral artery and vein; by its *deep surface*, with the Adductores brevis and magnus, the anterior branches of the obturator nerve, and with the profunda artery and vein near its insertion; by its *outer border*, with the Pectineus; by its *inner border*, with the Gracilis.

The Pectineus and Adductor longus should now be divided near their origin, and turned downward, when the Adductor brevis and Obturator externus will be exposed.

The **Adductor brevis** (*m. adductor brevis*) (Fig. 385) is situated immediately behind the two preceding muscles. It is somewhat triangular in form, and *arises* by a narrow origin from the outer surface of the body and descending ramus of the os pubis, between the Gracilis and Obturator externus. Its fibres passing backward, outward, and downward, are *inserted*, by an aponeurosis, into the lower part of the line leading from the lesser trochanter to the linea aspera, and the upper part of the same line, immediately behind the Pectineus and upper part of the Adductor longus.

Relations.—By its *superficial surface*, with the Pectineus, Adductor longus, profunda femoris artery, and anterior branches of the obturator nerve; by its *deep surface*, with the Adductor magnus and posterior branch of the obturator nerve; by its *outer border*, with the internal circumflex artery, the Obturator externus, and conjoined tendon of the Psoas and Iliacus; by its *inner border*, with the Gracilis and Adductor magnus. This muscle is pierced, near its insertion, by the second or by the first and second perforating branches of the profunda femoris artery.

The Adductor brevis should now be cut away near its origin, and turned outward, when the entire extent of the Adductor magnus will be exposed.

The **Adductor magnus** (*m. adductor magnus*) (Fig. 385) is a large, triangular muscle forming a septum between the muscles on the inner and those on the back of the thigh. It *arises* from a small part of the descending ramus of the os pubis, from the ramus of the ischium, and from the outer margin of the inferior part of the tuberosity of the ischium. Those fibres which arise from the ramus of the os pubis are very short, horizontal in direction, and are *inserted* into the rough line leading from the great trochanter to the linea aspera, internal to the Gluteus maximus. They are considered by some a distinct muscle and called the **Adductor minimus**. The fibres taking origin from the ramus of the ischium are directed downward and outward with different degrees of obliquity, to be *inserted*, by means of a broad aponeurosis, into the linea aspera and the upper part of its internal prolongation below. The **internal portion** of the muscle, consisting principally of those fibres which *arise* from the tuberosity of the ischium, forms a thick fleshy mass consisting of coarse bundles which descend almost vertically, and terminate about the lower third of the thigh in a rounded tendon, which is *inserted* into the Adductor tubercle on the inner condyle of the femur, and is connected by a fibrous expansion to the line leading upward from the tubercle to the linea aspera. Between the two portions of the muscle an interval is left, tendinous in front and fleshy behind, for the passage of the femoral vessels from Hunter's canal into the popliteal space. The **external portion** of the muscle at its attachment to the femur presents three or four osseoponeurotic openings, formed by tendinous arches attached to the bone, from which muscle fibres arise. The three superior of these apertures are for the three perforating arteries, and the fourth, when it exists, is for the terminal branch of the profunda.

Relations.—By its *superficial surface*, with the Pectineus, Adductor brevis, Adductor longus, and the femoral and profunda vessels and obturator nerve; by its *deep surface*, with the great sciatic nerve, the Gluteus maximus, Biceps femoris, Semitendinosus, and Semimembranosus. By its *superior or shortest border* it lies parallel to the Quadratus femoris, the internal circumflex

artery passing between them; by its *internal* or *longer border*, with the Gracilis, Sartorius, and fascia lata; by its *external* or *attached border* it is inserted into the femur behind the Adductor brevis and Adductor longus, which separate it from the Vastus internus, and in front of the Gluteus maximus and short head of the Biceps femoris, which separate it from the Vastus externus.

Nerves.—The three Adductor muscles and the Gracilis are supplied by the third and fourth lumbar nerves through the obturator nerve; the Adductor magnus receiving an additional branch from the sacral plexus through the great sciatic. The Pectineus is supplied by the second, third, and fourth lumbar nerves through the femoral, and by the accessory obturator, from the third lumbar, when it exists. Occasionally it receives a branch from the obturator nerve.¹

Actions.—The Pectineus and three Adductors adduct the thigh powerfully; they are especially used in horseback riding, the flanks of the horse being grasped between the knees by the actions of these muscles. In consequence of the obliquity of their insertion into the linea aspera they rotate the thigh outward, assisting the external Rotators, and when the limb has been abducted they draw it inward, carrying the thigh across that of the opposite side. The Pectineus and Adductor brevis and longus assist the Psoas and Iliacus in flexing the thigh upon the pelvis. In progression, also, all these muscles assist in drawing forward the hinder limb. The Gracilis assists the Sartorius in flexing the leg; it is also an adductor of the thigh. If the lower extremities are fixed, these muscles may take their fixed point from below and act upon the pelvis, serving to maintain the body in an erect posture, or, if their action is continued, to flex the pelvis forward upon the femur.

Hunter's Canal (*canalis adductorius* [*Hunteri*]) extends from the apex of Scarpa's triangle to the opening in the Adductor magnus muscle. The *antero-internal boundary* or *roof* of Hunter's canal is the Sartorius and the aponeurotic expansion from the Adductors to the Vastus internus. It is bounded *externally* by the Vastus internus. The Adductor longus and magnus constitute its *floor* or the *postero-internal boundary*. The canal contains the femoral artery, femoral vein, the long saphenous nerve, and the nerve to the Vastus internus.

Applied Anatomy.—The Adductor longus is liable to be severely *strained* in those who ride much on horseback, or its tendons to be *ruptured* by suddenly gripping the saddle. Occasionally, especially in cowboys and cavalry soldiers, the tendon of insertion of the Adductor magnus may become ossified, constituting the *rider's bone*.

III. MUSCLES AND FASCIÆ OF THE HIP.

3. The Gluteal Region (Figs. 387, 388).

Gluteus maximus.	Obturator internus.
Gluteus medius.	Gemellus superior.
Gluteus minimus.	Gemellus inferior.
Pyriformis.	Quadratus femoris.
	Obturator externus.

Dissection (Fig. 386).—The subject should be turned on its face, a block placed beneath the pelvis to make the buttocks tense, and the limbs allowed to hang over the end of the table, with the foot inverted and the thigh abducted. Make an incision through the integument along the crest of the ilium to the middle of the sacrum, and thence downward to the tip of the coccyx, and carry a second incision from that point obliquely downward and outward to the outer side of the thigh, four inches below the great trochanter. The portion of integument included between these incisions is to be removed in the direction shown in the figure.

The **Gluteus maximus** (*m. gluteus maximus*) (Fig. 387), the most superficial muscle in the gluteal region, is a very broad and thick, fleshy mass of a quadrilateral shape, which forms the prominence of the buttock. Its large size is one of the most characteristic points in the muscular system of man, connected as it is with the power he has of maintaining the trunk in the erect posture. In structure the muscle is remarkably coarse, being made up of muscle fasciculi lying parallel

¹ Professor Paterson describes the Pectineus as consisting of two incompletely separated strata, of which the outer or dorsal stratum, which is constant, is supplied by the femoral nerve, or in its absence by the accessory obturator, with which it is intimately related; while the inner or ventral stratum, when present, is supplied by the obturator nerve.—Journ. of Anat. and Phys., vol. xxvi, p. 43.

to one another, and collected into large bundles, separated by deep cellular intervals. It *arises* from the superior curved line of the ilium, and the portion of bone, including the crest, immediately above and behind it; from the posterior surface of the lower part of the sacrum, the side of the coccyx, the aponeurosis of the Erector spinae muscle, the great sacrosciatic ligament, and the fascia covering the Gluteus medius. The fibres are directed obliquely downward and outward; those forming the upper and large portion of the muscle, together with the superficial fibres of the lower portion, terminate in a thick tendinous lamina, which passes across the great trochanter and is *inserted* into the fascia lata covering the outer side of the thigh; the deeper fibres of the lower portion of the muscles are *inserted* into the rough line leading from the great trochanter to the linea aspera between the Vastus externus and Adductor magnus.

FIG. 386.—Dissection of lower extremity. Posterior view.

rotator muscles beneath. The upper portion of the muscle is to be altogether detached, and the lower portion turned outward; the loose areolar tissue filling up the interspace between the trochanter major and tuberosity of the ischium being removed, the parts already enumerated as exposed by the removal of this muscle will be seen.

The **Gluteus medius** (*m. gluteus medius*) (Fig. 387) is a broad, thick, radiating muscle, situated on the outer surface of the pelvis. Its posterior third is covered by the Gluteus maximus; its anterior two-thirds by the fascia lata, which separates it from the integument. It *arises* from the outer surface of the ilium, between the superior and middle curved lines, and from the outer lip of that portion of the crest which is between them; it also *arises* from the dense fascia, the *gluteal aponeurosis*, covering its outer surface. The fibres converge to a strong flattened

Relations.—By its *superficial surface*, with a thin fascia, which separates it from the subcutaneous tissue; by its *deep surface*, from above downward, with the ilium, sacrum, coccyx, and great sacrosciatic ligament, part of the Gluteus medius, Piriformis, Gemelli, Obturator internus, Quadratus femoris, the tuberosity of the ischium, great trochanter, the origin of the Biceps femoris, Semitendinosus, Semimembranosus, and Adductor magnus muscles. The superficial part of the gluteal artery reaches the deep surface of the muscle by passing between the Piriformis and the Gluteus medius; the sciatic and internal pudic vessels and nerves and muscular branches from the sacral plexus issue from the pelvis below the Piriformis. The first perforating artery and the terminal branches of the internal circumflex artery are also found under cover of the muscle. Its *upper border* is thin, and connected with the Gluteus medius by the fascia lata. Its *lower border* is free and prominent.

Several **synovial bursæ** are found in relation with this muscle. One of these (*bursa trochanterica m. glutei maximi*), of large size, and generally multilocular, separates it from the great trochanter. A second (*bursa ischiadica m. glutei maximi*), often wanting, is situated on the tuberosity of the ischium. A third bursa is found between the tendon of this muscle and the Vastus externus. Two or three small bursæ (*bursæ gluteofemorales*) are placed between the tendon of the muscle and that of the Vastus externus.

Dissection.—Divide the Gluteus maximus near its origin by a vertical incision carried from its upper to its lower border; a cellular interval will be exposed, separating it from the Gluteus medius and External

tendon which is *inserted* into the oblique line which traverses the outer surface of the great trochanter.

Relations.—By its *superficial surface*, with the Gluteus maximus behind, the Tensor fasciae femoris and deep fascia in front; by its *deep surface*, with the Gluteus minimus and the gluteal vessels and superior gluteal nerve. Its *anterior border* is blended with the Gluteus minimus. Its *posterior border* lies parallel to the Piriformis, the gluteal vessels intervening.

A **synovial bursa** (*bursa trochanterica m. glutei medii anterior*) separates the tendon of the muscle from the summit of the great trochanter. There is frequently a bursa (*bursa trochanterica m. glutei medii posterior*) between the tendons of the Gluteus medius and Piriformis.

This muscle should now be divided near its insertion and turned upward, when the Gluteus minimus will be exposed.

The **Gluteus minimus** (*m. gluteus minimus*) (Fig. 387), the smallest of the three Glutei, is placed immediately beneath the preceding. It is fan-shaped, *arising* from the outer surface of the ilium, between the middle and inferior curved lines, and behind, from the margin of the great sacrosciatic notch; the fibres converge to the deep surface of a radiated aponeurosis, which, terminating in a tendon, is *inserted* into an impression on the anterior border of the great trochanter.

Relations.—By its *superficial surface*, with the Gluteus medius and the gluteal vessels and superior gluteal nerve; by its *deep surface*, with the ilium, the reflected tendon of the Rectus femoris, and the capsular ligament of the hip-joint. Its *anterior margin* is blended with the Gluteus medius; its *posterior margin* is in contact and sometimes joined with the tendon of the Piriformis. There is a synovial **bursa** (*bursa m. glutei minimi*) between the tendon of the Gluteus minimus and the great trochanter.

The **Piriformis** (*m. piriformis*) (Figs. 387 and 388) is a flat muscle, pyramidal in shape, lying almost parallel with the posterior margin of the Gluteus medius. It is situated partly within the pelvis at its posterior part and partly at the back of the hip-joint. It *arises* from the front of the sacrum by three fleshy digitations attached to the portions of bone between the first, second, third, and fourth anterior sacral foramina, and also from the grooves leading from the foramina; a few fibres also *arise* from the margin of the great sacrosciatic foramen and from the anterior surface of the great sacrosciatic ligament. The muscle passes out of the pelvis through the great sacrosciatic foramen, the upper part of which it fills, and is *inserted* by a rounded tendon into the inner side of the upper border of the great trochanter, behind, but often partly blended with, the tendon of the Obturator internus and Gemelli muscles.

Relations.—By its *deep surface*, *within the pelvis*, with the rectum (especially on the left side), the sacral plexus of nerves, and the branches of the internal iliac vessels; *external to the pelvis*, with the posterior surface of the ischium and the capsular ligament of the hip-joint; by its *superficial surface*, *within the pelvis*, with the sacrum, and *external to it*, with the Gluteus maximus; by its *upper border*, with the Gluteus medius, from which it is separated by the gluteal vessels and superior gluteal nerve; by its *lower border*, with the Gemellus superior and Coccygeus, the sciatic vessels and nerves, the internal pudic vessels and nerve, and muscular branches from the sacral plexus, passing from the pelvis in the interval between the two muscles.

The **Obturator Membrane** (*membrana obturatoria*) (Fig. 240) is a thin layer of interlacing fibres which closes almost completely the obturator foramen. It is attached, externally, to the margin of the foramen; internally, to the posterior surface of the ischiopubic ramus, below and internal to the margin of the foramen. It presents at its upper and outer parts a small canal, **obturator canal** (*canalis obturatorius*) for the passage of the obturator vessels and nerve. Both obturator muscles are connected with this membrane.

There is usually a **bursa** (*bursa m. piriformis*) between the tendon of the Piriformis and the ilium.

Dissection.—The next muscle, as well as the origin of the Piriformis, can only be seen when the pelvis is divided and the viscera removed.

FIG. 387.—Muscles of the hip and thigh.

The **Obturator internus** (*m. obturator internus*) (Figs. 387 and 388), like the preceding muscle, is situated partly within the cavity of the pelvis, and partly at the back of the hip-joint. It *arises* from the inner surface of the anterior and external wall of the pelvis, where it surrounds the greater part of the obturator foramen, being attached to the descending ramus of the os pubis and the ramus of the ischium, and at the side to the inner surface of the innominate bone below and behind the pelvic brim, reaching from the upper part of the great sacrospinous foramen above and behind to the obturator foramen below and in front. It also *arises* from the inner surface of the obturator membrane except at its posterior part, from the tendinous arch which completes the canal for the passage of the obturator vessels and nerve and to a slight extent from the obturator layer of the pelvic fascia, which covers it. The fibres converge rapidly, and are directed backward and downward, and terminate in four or five tendinous bands, which are found on its deep surface; these bands are reflected at a right angle over the inner surface of the tuberosity of the ischium, which is grooved for their reception; the groove is covered by cartilage, and lined with a synovial bursa (*bursa m. obturatoris interni*). The muscle leaves the pelvis by the lesser sacrospinous foramen; and the tendinous bands unite into a single flattened tendon, which passes horizontally outward, and, after receiving the attachment of the Gemelli, is *inserted* into the fore part of the inner surface of the great trochanter in front of the Obturator externus.

In order to display the peculiar appearances presented by the tendon of this muscle, it must be divided near its insertion and reflected inward.

Relations.—*Within the pelvis* this muscle is in relation, by its *deep surface*, with the obturator membrane and inner surface of the anterior wall of the pelvis; by its *superficial surface*, with the pelvic and obturator fasciæ, which separate it from the Levator ani; and it is crossed by the internal pudic vessels and nerve. This surface forms the outer boundary of the ischio-

FIG. 388.—Muscles of the small or true pelvis on the right side, viewed from without and below. (Spalteholz.)

rectal fossa. *External to the pelvis* it is covered by the Gluteus maximus, is crossed by the great sciatic nerve, and rests on the back part of the hip-joint. As the tendon of the Obturator internus emerges from the lesser sacrosclatic foramen it is overlapped by the two Gemelli, while nearer its insertion the Gemelli pass in front of it and form a groove in which the tendon lies. A synovial **bursa**, narrow and elongated in form, is usually found between the tendon of this muscle and the capsular ligament of the hip; it occasionally communicates with the bursa between the tendon and the tuberosity of the ischium, the two forming a single sac.

The **Gemelli** (Fig. 377) are two small muscular fasciculi, accessories to the tendon of the Obturator internus, which is received into a groove between them. They are called **superior** and **inferior**.

The **Gemellus superior** (*m. gemellus superior*), the smaller of the two, *arises* from the outer surface of the spine of the ischium, and, passing horizontally outward, becomes blended with the upper part of the tendon of the Obturator internus, and is *inserted* with it into the inner surface of the great trochanter. This muscle is sometimes wanting.

Relations.—By its *superficial surface*, with the Gluteus maximus and the sciatic vessels and nerves; by its *deep surface*, with the capsule of the hip-joint; by its *upper border*, with the lower margin of the Piriformis; by its *lower border*, with the tendon of the Obturator internus.

FIG. 389.—Obturator externus muscle. (From a preparation in the Museum of the Royal College of Surgeons of England.)

The **Gemellus inferior** (*m. gemellus inferior*) *arises* from the upper part of the tuberosity of the ischium, where it forms the lower edge of the groove for the Obturator internus tendon, and, passing horizontally outward, is blended with the lower part of the tendon of the Obturator internus, and is *inserted* with it into the inner surface of the great trochanter.

Relations.—By its *superficial surface*, with the Gluteus maximus and the sciatic vessels and nerves; by its *deep surface*, with the capsular ligament of the hip-joint; by its *upper border*, with the tendon of the Obturator internus; by its *lower border*, with the tendon of the Obturator externus and Quadratus femoris.

The **Quadratus femoris** (*m. quadratus femoris*) (Fig. 387) is a short, flat muscle, quadrilateral in shape, situated between the Gemellus inferior and the upper margin of the Adductor magnus. It *arises* from the upper part of the external lip of the tuberosity of the ischium, and, proceeding horizontally outward, is

inserted into the upper part of the linea quadrata; that is, the line which crosses the posterior intertrochanteric line.

Relations.—By its *superficial surface*, with the Gluteus maximus and the sciatic vessels and nerves; by its *deep surface*, with the tendon of the Obturator externus and trochanter minor and with the capsule of the hip-joint; by its *upper border*, with the Gemellus inferior. Its *lower border* is separated from the Adductor magnus by the terminal branches of the internal circumflex vessels. A synovial bursa is often found between the under surface of this muscle and the lesser trochanter, which it covers.

Dissection.—In order to expose the next muscle (the Obturator externus) it is necessary to remove the Psoas, Iliacus, Pectineus, and Adductores brevis and longus muscles from the front and inner side of the thigh, and the Gluteus maximus and Quadratus femoris from the back part. Its dissection should, consequently, be postponed until the muscles of the anterior and internal femoral regions have been explained.

The **Obturator externus** (*m. obturator externus*) (Figs. 388 and 389) is a flat, triangular muscle, which covers the outer surface of the anterior wall of the pelvis. It *arises* from the margin of bone immediately around the inner side of the obturator foramen—viz., from the body and ramus of the os pubis and the ramus of the ischium; it also *arises* from the inner two-thirds of the outer surface of the obturator membrane, and from the tendinous arch which completes the canal for the passage of the obturator vessels and nerves. The fibres from the pubic arch extend on to the inner surface of the bone, from which they obtain a narrow origin between the margin of the foramen and the attachment of the membrane. The fibres converging pass backward, outward, and upward, and terminate in a tendon which runs across the back part of the hip-joint, and is *inserted* into the digital fossa of the femur.

Relations.—In *front*, with the Psoas, Iliacus, Pectineus, Adductor magnus, and Adductor brevis; and more externally, with the neck of the femur and capsule of the hip-joint. The external and internal terminal branches of the obturator artery and accompanying veins lie between this muscle and the obturator membrane; the superficial part of the obturator nerve lies above the muscle, and the deep branch perforates it; by its *deep surface*, with the obturator membrane and Quadratus femoris at its insertion.

Nerves.—The Gluteus maximus is supplied by the fifth lumbar and first and second sacral nerves through the inferior gluteal nerve from the sacral plexus; the Gluteus medius and minimus, by the fourth and fifth lumbar and first sacral nerves, through the superior gluteal; the Piriformis is supplied by the first and second sacral nerves; the Gemellus inferior and Quadratus femoris by the last lumbar and first sacral nerve; the Gemellus superior and Obturator internus by the fifth lumbar and first and second sacral nerves, and the Obturator externus by the second, third, and fourth lumbar nerves through the obturator nerve.

Actions.—The Gluteus maximus, when it takes its fixed point from the pelvis, extends the femur and brings the bent thigh into a line with the body. Taking its fixed point from below, it acts upon the pelvis, supporting it and the whole trunk upon the head of the femur, which is especially obvious in standing on one leg. Its most powerful actions are to hold the head of the femur in close approximation to the acetabulum in walking and to cause the body to regain the erect position after stooping by drawing the pelvis backward, being assisted in this action by the Biceps, Semitendinosus, and Semimembranosus. The Gluteus maximus is a tensor of the fascia lata, and by its connection with the iliotibial band it steadies the femur on the articular surface of the tibia during standing, when the Extensor muscles are relaxed. The lower part of the muscle also acts as an Adductor and External rotator of the limb. The Gluteus medius and minimus abduct the thigh when the limb is extended, and are principally called into action in supporting the body on one limb, in conjunction with the Tensor fasciae femoris. Their anterior fibres, by drawing the great trochanter forward, rotate the thigh inward, in which action they are also assisted by the Tensor fasciae femoris. The remaining muscles are powerful Rotators of the thigh outward. In the sitting posture, when the thigh is flexed upon the pelvis, their action as Rotators cease, and they become Abductors, with the exception of the Obturator externus, which still rotates the femur outward. When the femur is fixed, the Piriformis and Obturator muscles serve to draw the pelvis forward if it has been inclined backward, and assist in steadying it upon the head of the femur.

4. The Posterior Femoral Region.

(Hamstring Muscles.)

Biceps femoris.

Semitendinosus.

Semimembranosus.

Dissection (Fig. 386).—Make a vertical incision along the middle of the back of the thigh, from the lower fold of the buttock to about three inches below the back of the knee-joint, and there connect it with a transverse incision, carried from the inner to the outer side of the leg. Make a third incision transversely at the junction of the middle with the lower third of the thigh. The integument having been removed from the back of the knee, and the boundaries of the popliteal space having been examined, the removal of the integument from the remaining part of the thigh should be continued, when the fascia and muscles of this region will be exposed.

FIG. 390.—Diagram showing the attachments of the muscles of the thigh. Posterior aspect. Origins, red; insertions, blue.

The **Biceps femoris** (*m. biceps femoris*) is a large muscle, of considerable length, situated on the posterior and outer aspect of the thigh (Figs. 387 and 391). It arises by two heads. One, the **long head** (*caput longum*), arises from the lower and inner impression on the back part of the tuberosity of the ischium, by a tendon

common to it and the Semitendinosus, and from the lower part of the great sacro-sciatic ligament. The femoral or short head (*caput breve*) arises from the outer lip of the linea aspera, between the Adductor magnus and Vastus externus, extending up almost as high as the insertion of the Gluteus maximus; from the outer prolongation of the linea aspera to within two inches of the outer condyle, and from the external intermuscular septum. The fibres of the long head form a fusi-

FIG. 391.—Region of the knee, seen obliquely from behind and within. Right limb. (Toldt.)

form belly, which, passing obliquely downward and a little outward, terminates in an aponeurosis which covers the posterior surface of the muscle, and receives the fibres of the short head; this aponeurosis becomes gradually contracted into a tendon, which is inserted into the outer side of the head of the fibula, and by a small slip into the lateral surface of the external tuberosity of the tibia. At its insertion the tendon divides into two portions, which embrace the long external lateral ligament of the knee-joint. From the posterior border of the tendon a

thin expansion is given off to the fascia of the leg. The tendon of this muscle forms the **outer Hamstring**.

Relations.—By its *superficial surface*, with the Gluteus maximus and the small sciatic nerve, the fascia lata, and integument. By its *deep surface*, with the Semimembranosus, Adductor magnus, and Vastus externus, the great sciatic nerve, and, near its insertion, with the external head of the Gastrocnemius, the Plantaris, the superior external articular artery, and the external popliteal nerve. A bursa (*bursa m. bicipitis femoris inferior*) is found between the long tendon of origin of this muscle and the Semitendinosus and Semimembranosus. Sometimes there is a bursa (*bursa bicipitogastrocnemialis*) between the tendon of the insertion of the Biceps and the origin of the Gastrocnemius, and there is a bursa (*bursa m. bicipitis femoris inferior*) between the tendon of the Biceps and the external lateral ligament.

The **Semitendinosus** (*m. semitendinosus*) (Figs. 387 and 391), remarkable for the great length of its tendon, is situated at the posterior and inner aspect of the thigh. It *arises* from the lower and inner impression on the tuberosity of the ischium by a tendon common to it and the long head of the Biceps femoris; it also *arises* from an aponeurosis which connects the adjacent surfaces of the two muscles to the extent of about three inches after their origin. The Semitendinosus is a fusiform muscle, which, passing downward and inward, terminates a little below the middle of the thigh in a long round tendon which lies along the inner side of the popliteal space, then curves around the inner tuberosity of the tibia, and is *inserted* into the upper part of the inner surface of the shaft of that bone nearly as far forward as its anterior border. At its insertion it gives off from its lower border a prolongation to the deep fascia of the leg. This tendon lies behind the tendon of the Sartorius, and below that of the Gracilis, to which it is united. A tendinous intersection is usually observed about the middle of the muscles. The **bursa anserina** lies between the tendon of the Semitendinosus and the tibia.

The **Semimembranosus** (*m. semimembranosus*) (Figs. 387 and 391), so called from its membranous tendon of origin, is situated at the back part and inner side of the thigh. It *arises* by a thick tendon from the upper and outer impression on the back part of the tuberosity of the ischium, above and to the outer side of the Biceps femoris and Semitendinosus, and is *inserted* into the groove on the inner and back part of the inner tuberosity of the tibia, beneath the internal lateral ligament. The tendon of the muscle at its origin expands into an aponeurosis which covers the upper part of its anterior surface; from this aponeurosis muscle fibres arise, and converge to another aponeurosis, which covers the lower part of its posterior surface and contracts into the tendon of insertion. The tendon of the muscle at its insertion gives off certain fibrous expansions; one of these, of considerable size, passes upward and outward, to be *inserted* into the back part of the outer condyle of the femur, forming part of the posterior ligament of the knee-joint; a second is continued downward to the fascia which covers the Popliteus muscle. The tendon also sends a few fibres to join the internal lateral ligament of the joint.

The tendons of the two preceding muscles, with that of the Gracilis, form the **inner Hamstrings**.

Nerves.—The muscles of this region are supplied by the fourth and fifth lumbar and the first, second, and third sacral nerves through the great sciatic nerve.

Actions.—The Hamstring muscles flex the leg upon the thigh. When the knee is semiflexed, the Biceps, in consequence of its oblique direction downward and outward, rotates the leg slightly outward; and the Semitendinosus, and to a slight extent the Semimembranosus, rotate the leg inward, assisting the Popliteus. Taking their fixed point from below, these muscles, especially the Semimembranosus, serve to support the pelvis upon the head of the femur and to draw the trunk directly backward, as in raising it from the stooping position or in feats of strength, when the body is thrown backward in the form of an arch. When the leg is extended on the thigh, they limit the amount of flexion of the trunk on the lower limbs.

Applied Anatomy.—The Hamstring tendons are occasionally *ruptured*. In disease of the knee-joint the Hamstrings may *contract*, flexing the knee, drawing the tibia backward, and sometimes causing incomplete dislocation. The tendons of these muscles occasionally require *subcutaneous division* in some forms of *spurious ankylosis* of the knee-joint dependent upon permanent contraction and rigidity of the Flexor muscles, or from stiffening of the ligamentous other tissues surrounding the joint, the result of disease. Division of a tendon is effected by putting the tendon upon the stretch, and inserting a narrow sharp-pointed knife between it and the skin; the cutting edge being then turned toward the tendon, it should be divided, taking great care that the wound in the skin is not at the same time enlarged. The relation of the external popliteal nerve to the tendon of the Biceps must always be borne in mind in dividing this tendon; in fact, a complete exposure of the tendon is much to be preferred.

IV. MUSCLES AND FASCIÆ OF THE LEG.

These may be divided into three groups: those on the **anterior**, those on the **posterior**, and those on the **outer side of the leg**.

5. The Anterior Tibiofibular Region (Fig. 393).

Tibialis anticus.

Extensor proprius hallucis.¹

Extensor longus digitorum.

Peroneus tertius.

Dissection (Fig. 379).—The knee should be bent, a block placed beneath it, and the foot kept in an extended position; then make an incision through the integument in the middle line of the leg to the ankle, and continue it along the dorsum of the foot to the toes. Make a second incision transversely across the ankle, and a third in the same direction across the bases of the toes; remove the flaps of integument included between these incisions in order to examine the deep fascia of the leg.

The **deep fascia of the leg** (*fascia cruris*) forms a complete investment to the muscles, but is not continuous over the subcutaneous surfaces of the bones. It is continuous *above* with the fascia lata, receiving an expansion from the tendon of the Biceps femoris, on the outer side, and from the tendons of the Sartorius Gracilis, and Semitendinosus on the inner side; in *front*, it blends with the periosteum covering the subcutaneous surface of the tibia, and with that covering the head and external malleolus of the fibula; *below*, it is continuous with the annular ligaments of the ankle. It is thick and dense in the upper and anterior part of the leg, and gives attachment, by its deep surface, to the Tibialis anticus and Extensor longus digitorum muscles, but is thinner behind, where it covers the Gastrocnemius and Soleus muscles. Over the popliteal space it is much strengthened by transverse fibres which stretch across from the inner to the outer Hamstring muscles, and it is here perforated by the external saphenous vein. Its deep surface gives off, on the outer side of the leg, two strong intermuscular septa which enclose the Peronei muscles, and separate them from the muscles of the anterior and posterior tibial regions. It also gives off several smaller and more slender processes which enclose the individual muscles in each region; at the same time a broad transverse, intermuscular septum, called the **deep transverse fascia of the leg**, intervenes between the superficial and deep muscles in the posterior tibiofibular region.

¹There is no such word as "Hallux, -cis." It is the result of some ignorant blunder, copied until it has become established by usage; it has been thought better, therefore, to retain it. According to Lewis and Short, the word is ALLEX, masculine; genitive, ALLICIS, the great toe, and the correct rendering would be Extensor proprius allicis. It is a rare word, and is sometimes spelt, but not so correctly, "Hallex." It is used by Plautus, in the "Poenulus," V. v. 31. of a little man, as we might say, "a hop-o'-my-thumb." "Tunc hic anator aude esse, allex viri" (To think of you daring to make up to her, you hop-o'-my-thumb!). The word "alex," sometimes spelt "allex," a fish sauce, is probably a different word altogether. It is used by Horace and Pliny.

Remove the fascia by dividing it in the same direction as the integument, excepting opposite the ankle, where it should be left entire. Commence the removal of the fascia from below, opposite the tendons, and detach it in the line of direction of the muscle fibres.

The **Tibialis anticus** (*m. tibialis anterior*) is situated on the outer side of the tibia; it is thick and fleshy at its upper part, tendinous below. It *arises* from the outer tuberosity and upper two-thirds of the external surface of the shaft of the tibia; from the adjoining part of the interosseous membrane; from the deep surface

FIG. 392.—Diagram showing the attachments of the muscles of the leg. Anterior aspect. Origins, red; insertions, blue.

of the fascia; and from the intermuscular septum between it and the Extensor longus digitorum; the fibres pass vertically downward, and terminate in a tendon which is apparent on the anterior surface of the muscle at the lower third of the leg. After passing through the innermost compartment of the anterior annular ligament, it is *inserted* into the inner and under surface of the internal cuneiform bone and base of the metatarsal bone of the great toe. There is usually a *bursa* (*bursa subtendinea m. tibialis anterioris*) between the tendon of the Tibialis anticus and the internal cuneiform bone. At the upper part of the leg this muscle overlaps the anterior tibial vessels and nerve.

The **Extensor proprius hallucis** (*m. extensor hallucis longus*) is a thin, elongated, and flattened muscle situated between the Tibialis anticus and Extensor longus digitorum. It *arises* from the anterior surface of the fibula for about the middle two-fourths of its extent, its origin being internal to that of the Extensor longus digitorum; it also *arises* from the interosseous membrane to a similar extent. The fibres pass downward, and terminate in a tendon which occupies the anterior border of the muscle, passes through a distinct compartment in the lower portion of the annular ligament, crosses the anterior tibial vessels near the bend of the ankle, and is *inserted* into the base of the last phalanx of the great toe. Opposite the metatarsophalangeal articulation the tendon gives off a thin prolongation on each side, which covers the surface of the joint. It usually sends an expansion from the inner side of the tendon, to be inserted into the base of the first phalanx.

The **Extensor longus digitorum** (*m. extensor digitorum longus*) is an elongated, flattened, penniform muscle situated the most externally of all the muscles on the fore part of the leg. It *arises* from the outer tuberosity of the tibia; from the upper three-fourths of the anterior surface of the shaft of the fibula; from the interosseous membrane; from the deep surface of the fascia; and from the intermuscular septa between it and the Tibialis anticus on the inner and the Peronei on the outer side. The tendon enters a canal in the annular ligament with the Peroneus tertius, and divides into four slips, which run across the dorsum of the foot and are *inserted* into the second and third phalanges of the four lesser toes. The mode in which the tendons are inserted is the following: Each of the three inner tendons opposite the metatarsophalangeal articulation is joined, on its outer side, by a tendon from the Extensor brevis digitorum. The outer tendon does not receive such a tendinous slip. They all receive a fibrous expansion from the Interossei and Lumbricales, and then spread out into a broad aponeurosis, which covers the dorsal surface of the first phalanx; this aponeurosis, at the articulation of the first with the second phalanx, divides into three slips—a middle one, which is inserted into the base of the second phalanx, and two lateral slips, which, after uniting on the dorsal surface of the second phalanx, are continued onward, to be inserted into the base of the third.

The **Peroneus tertius** (*m. peroneus tertius*) is a part of the Extensor longus digitorum, and might be described as its fifth tendon. The fibres belonging to this tendon *arise* from the lower fourth of the anterior surface of the fibula, from the lower part of the interosseous membrane, and from an intermus-

FIG. 393.—Muscles of the front of the leg.

cular septum between it and the Peroneus brevis. The tendon, after passing through the same canal in the annular ligament as the Extensor longus digitorum, is *inserted* into the dorsal surface of the base of the metatarsal bone of the little toe. This muscle is sometimes wanting.

Nerves.—These muscles are supplied by the fourth and fifth lumbar and first sacral nerves through the anterior tibial nerve.

Actions.—The Tibialis anticus and Peroneus tertius are the direct Flexors of the foot at the ankle-joint; the former muscle, when acting in conjunction with the Tibialis posticus, raises the inner border of the foot (*i. e.*, inverts the foot); and the latter, acting with the Peroneus brevis and longus, draws the outer border of the foot upward, and the sole outward (*i. e.*, everts the foot). The Extensor longus digitorum and Extensor proprius hallucis extend the phalanges of the toes, and, continuing their action, flex the foot upon the leg. Taking their fixed point from below, in the erect posture, all these muscles serve to fix the bones of the leg in the perpendicular position, and give increased strength to the ankle-joint.

6. The Posterior Tibiofibular Region (Figs. 391, 396).

Dissection (Fig. 386).—Make a vertical incision along the middle line of the back of the leg, from the lower part of the popliteal space to the heel, connecting it below by a transverse incision extending between the two malleoli; the flaps of integument being removed, the fascia and muscles should be examined.

The muscles in this region of the leg are subdivided into two layers—**superficial** and **deep**. The superficial layer constitutes a powerful muscular mass, forming the calf of the leg. Their large size is one of the most characteristic features of the muscular apparatus in man, and bears a direct connection with his ordinary attitude and mode of progression.

The Superficial Layer.

Gastrocnemius.

Soleus.

Plantaris.

The **Gastrocnemius** (*m. gastrocnemius*) is the most superficial muscle, and forms the greater part of the calf. It *arises* by two heads, which are connected to the condyles of the femur by two strong flat tendons. The **inner** and larger head (*caput mediale*) *arises* from a depression at the upper and back part of the inner condyle and from the adjacent part of the femur. The **outer head** (*caput laterale*) *arises* from an impression on the outer side of the external condyle and from the posterior surface of the femur immediately above the condyle. Both heads, also, *arise* by a few tendinous and fleshy fibres from the ridges which are continued upward from the condyles to the lineæ asperæ. Each tendon spreads out into an aponeurosis, which covers the posterior surface of that portion of the muscle to which it belongs; the muscle fibres of the inner head form a thicker mass and extend lower than those of the outer. From the anterior surface of these tendinous expansions muscle fibres are given off. The fibres in the median line, which correspond to the accessory portions of the muscle derived from the bifurcations of the lineæ asperæ, unite at an angle upon a median tendinous raphe below; the remaining fibres converge to an aponeurosis which covers the anterior surface of the muscle, and this, gradually contracting, unites with the tendon of the Soleus, and forms with it the *tendo Achillis*.

Relations.—By its *superficial surface*, with the fascia of the leg, which separates it from the external saphenous vein and nerve; by its *deep surface*, with the posterior ligament of the knee-joint, the Popliteus, Soleus, Plantaris, popliteal vessels, and internal popliteal nerve. The tendon of the inner head corresponds with the back part of the inner condyle, from which it is

FIG. 394.—Diagram showing the attachments of muscles of leg. Posterior aspect. Origins, red; insertions, blue. The attachments of muscles of bones of foot are given in detail in Figs. 191 and 192.

separated by a synovial bursa, which, in some cases, communicates with the cavity of the knee-joint. The tendon of the outer head contains a sesamoid fibrocartilage (rarely osseous), where it plays over the corresponding outer condyle; and one is occasionally in the tendon of the inner head.

The Gastrocnemius should be divided across, just below its origin, and turned downward, in order to expose the next two muscles.

The **Soleus** (*m. soleus*) is a broad flat muscle situated immediately beneath the Gastrocnemius. It has received its name from its resemblance in shape to a sole-fish. It arises by tendinous fibres from the back part of the head of the fibula and from the upper third of the posterior surface of its shaft; from the oblique line of the tibia and from the middle third of its internal border; some fibres also arise from a tendinous arch placed between the tibial and fibular origins of the muscle, beneath which the popliteal vessels and internal popliteal nerve pass. The fibres pass backward

FIG. 395.—Bursa of the tendo Achillis. (Poirier and Charpy.)

The fibres pass backward to an aponeurosis which covers the posterior surface of the muscle, and this,

gradually becoming thicker and narrower, joins with the tendon of the Gastrocnemius, and forms with it the tendo Achillis.

Relations.—By its *superficial surface*, with the Gastrocnemius and Plantaris; by its *deep surface*, with the Flexor longus digitorum, Flexor longus hallucis, Tibialis posticus, and posterior tibial vessels and nerve, from which it is separated by the transverse intermuscular septum or deep transverse fascia of the leg.

The **Tendo Achillis** (*tendo calcaneus*), the common tendon of the Gastrocnemius and Soleus,¹ is the thickest and strongest tendon in the body. It is about six inches in length, and *commences* about the middle of the leg, but receives fleshy fibres on its anterior surface nearly to its lower end. Gradually becoming contracted below, it is *inserted* into the lower part of the posterior surface of the os calcis, a synovial bursa (*bursa tendinis calcanei* [*Achillis*]) (Fig. 395) being interposed between the tendon and the upper part of this surface. The tendon spreads out somewhat at its lower end, so that its narrowest part is usually about an inch and a half above its insertion. The tendon is covered by the fascia and the integument, a bursa (*bursa subcutanea calcanea*) (Fig. 395) being often interposed between the tendon and the fascia. The tendon is separated from the deep muscles and vessels by a considerable interval filled up with areolar and adipose tissues. Along its outer side, but superficial to it, is the external saphenous vein.

The **Plantaris** (*m. plantaris*) is an extremely diminutive muscle placed between the Gastrocnemius and Soleus, and remarkable for its long and delicate tendon. It *arises* from the lower part of the outer prolongation of the linea aspera and from the posterior ligament of the knee-joint. It forms a small fusiform belly, about three or four inches in length, terminating in a long slender tendon which crosses obliquely between the two muscles of the calf, and, running along the inner border of the tendo Achillis, is *inserted* with it into the posterior part of the os calcis. This muscle is occasionally double, and is sometimes wanting. Occasionally its tendon is lost in the internal annular ligament or in the fascia of the leg.

Nerves.—The Gastrocnemius is supplied by the first and second sacral nerves, and the Plantaris by the fourth and fifth lumbar and first sacral nerves through the internal popliteal. The Soleus is supplied by the fifth lumbar and first and second sacral nerves through the internal popliteal and posterior tibial.

Actions.—The muscles of the calf are the chief Extensors of the foot at the ankle-joint. They possess considerable power, and are constantly called into use in standing, walking, dancing, and leaping; hence, the large size they usually present. In walking, these muscles draw powerfully upon the os calcis, raising the heel, and with it the entire body, from the ground; the body being thus supported on the raised foot, the opposite limb can be carried forward. In standing, the Soleus, taking its fixed point from below, steadies the leg upon the foot, and prevents the body from falling forward, to which there is a constant tendency from the superincumbent weight. The Gastrocnemius, acting from below, serves to flex the femur upon the tibia, assisted by the Popliteus. The Plantaris is the rudiment of a large muscle which exists in some of the lower animals and is continued over the os calcis to be inserted into the plantar fascia. In man it is an accessory to the Gastrocnemius, extending the ankle if the foot is free, or bending the knee if the foot is fixed. Possibly, acting from below, by its attachment to the posterior ligament of the knee-joint, it may pull that ligament backward during flexion, and so protect it from being compressed between the two articular surfaces.

The Deep Layer (Fig. 397).

Popliteus.

Flexor longus hallucis.

Flexor longus digitorum.

Tibialis posticus.

Dissection.—Detach the Soleus from its attachment to the fibula and tibia, and turn it downward, when the deep layer of muscles is exposed, covered by the deep transverse fascia of the leg.

¹ These two muscles with a common tendon are by some anatomists classed together as one muscle, the *Triceps surae*, the two heads of origin of the Gastrocnemius and the Soleus constituting the three heads of the Triceps, and the tendo Achillis the single tendon of insertion.

The **deep transverse fascia** of the leg is a transversely placed, intermuscular septum, between the superficial and deep muscles in the posterior tibiofibular

FIG. 396.—Muscles of the back of the right leg. Superficial layer.

FIG. 397.—Muscles of the back of the right leg. Deep layer.

region. On either side it is connected to the margins of the tibia and fibula. Above, where it covers the Popliteus, it is thick and dense, and receives an expansion from the tendon of the Semimembranosus; it is thinner in the middle of the

leg, but below, where it covers the tendons passing behind the malleoli, it is thickened and continuous with the internal annular ligament.

This fascia should now be removed, commencing from below opposite the tendons, and detaching it from the muscles in the direction of their fibres.

The **Popliteus** (*m. popliteus*) (Fig. 391) is a thin, flat, triangular muscle, which forms part of the floor of the popliteal space. It *arises* by a strong tendon, about an inch in length, from a deep depression on the outer side of the external condyle of the femur, and from the posterior ligament of the knee-joint. The muscle is *inserted* into the inner two-thirds of the triangular surface above the oblique line on the posterior surface of the shaft of the tibia, and into the tendinous expansion covering the surface of the muscle. The tendon of the muscle is covered by that of the Biceps femoris and by the external lateral ligament of the knee-joint; it grooves the posterior border of the external semilunar fibrocartilage, and is invested by the synovial membrane of the knee-joint.

Relations.—By its *superficial surface*, with the fascia covering it, which separates it from the Gastrocnemius, Plantaris, popliteal vessels, and internal popliteal nerve; by its *deep surface*, with the knee-joint and back of the tibia.

The **Flexor longus hallucis** (*m. flexor hallucis longus*) is situated on the fibular side of the leg, and is the most superficial and largest of the three next muscles. It *arises* from the lower two-thirds of the posterior surface of the shaft of the fibula, with the exception of an inch at its lowest part; from the lower part of the interosseous membrane; from an intermuscular septum between it and the Peronei, externally; and from the fascia covering the Tibialis posticus internally. The fibres pass obliquely downward and backward, and terminate in a tendon which occupies nearly the whole length of the posterior surface of the muscle. This tendon occupies a groove on the posterior surface of the lower end of the tibia; it then lies in a second groove on the posterior surface of the astragalus, and finally in a third groove, beneath the sustentaculum tali of the os calcis, and passes into the sole of the foot, where it runs forward between the two heads of the Flexor brevis hallucis, and is *inserted* into the base of the last phalanx of the great toe (Fig. 399). The grooves in the astragalus and os calcis, which contain the tendon of the muscle, are converted by tendinous fibres into distinct canals lined by synovial membrane; and as the tendon crosses the sole of the foot, it is connected to the Common Flexor by a tendinous slip.

Relations.—By its *superficial surface*, with the Soleus and tendo Achillis, from which it is separated by the deep transverse fascia; by its *deep surface*, with the fibula, Tibialis posticus, the peroneal vessels, the lower part of the interosseous membrane, and the ankle-joint; by its *outer border*, with the Peronei; by its *inner border*, with the Tibialis posticus and posterior tibial vessels and nerve. In the sole of the foot it lies above the Abductor hallucis and Flexor longus digitorum.

The **Flexor longus digitorum** (*m. flexor digitorum longus*) is situated on the tibial side of the leg. At its origin it is thin and pointed, but gradually increases in size as it descends. It *arises* from the posterior surface of the shaft of the tibia, immediately below the oblique line to within three inches of its extremity, internal to the tibial origin of the Tibialis posticus; some fibres also arise from the fascia covering the Tibialis posticus. The fibres terminate in a tendon which runs nearly the whole length of the superficial surface of the muscle. This tendon passes behind the internal malleolus in a groove, common to it and the Tibialis posticus, but separated from the latter by a fibrous septum, each tendon being contained in a special sheath lined by a separate synovial membrane. It then passes obliquely forward and outward, superficial to the internal lateral ligament, into the sole of

the foot (Fig. 399), where, crossing superficially to the tendon of the Flexor longus hallucis,¹ to which it is connected by a strong tendinous slip, it becomes expanded, is joined by the Flexor accessorius, and finally divides into four tendons, which are *inserted* into the bases of the last phalanges of the four lesser toes, each tendon passing through a fissure in the tendon of the Flexor brevis digitorum opposite the base of the first phalanges (Fig. 398).

Relations.—*In the leg*, by its *superficial surface*, with the posterior tibial vessels and nerve, and the deep transverse fascia, which separates it from the Soleus muscle; by its *deep surface*, with the Tibia and Tibialis posticus. *In the foot* it is covered by the Abductor hallucis and Flexor brevis digitorum, and crosses superficial to the Flexor longus hallucis.

The **Tibialis posticus** (*m. tibialis posterior*) lies between the two preceding muscles, and is the most deeply seated of all the muscles in the leg. It commences above by two pointed processes, separated by an angular interval, through which the anterior tibial vessels pass forward to the front of the leg. It *arises* from the whole of the posterior surface of the interosseous membrane, excepting its lowest part, from the outer portion of the posterior surface of the shaft of the tibia, between the commencement of the oblique line above, and the junction of the middle and lower third of the shaft below; and from the upper two-thirds of the internal surface of the fibula; some fibres also arise from the deep transverse fascia and from the intermuscular septa, separating it from the adjacent muscles on each side. This muscle, in the lower fourth of the leg, passes in front of the Flexor longus digitorum, and terminates in a tendon which passes through a groove behind the inner malleolus with the tendon of that muscle, but enclosed in a separate sheath; it then passes through another sheath, over the internal lateral ligament into the foot, and then beneath the inferior calcaneoscaphoid ligament. Beyond this sheath the tendon passes between the sustentaculum tali and the tubercle of the scaphoid to the plantar aspect and divides into two main slips. The *stronger medial* slip is *inserted* into the tubercle of the scaphoid and into the internal cuneiform and sends an expansion to the plantar surface of the sustentaculum tali. The *weaker lateral* slip divides into lesser slips, which are *inserted* into the middle and external cuneiform, the cuboid and the base of the second, third, and fourth metatarsal bones. The stronger tendon as it passes over the scaphoid contains a sesamoid bone. A bursa is often situated between the tendon and the scaphoid.

Relations.—By its *superficial surface*, with the Soleus, from which it is separated by the deep transverse fascia, the Flexor longus digitorum, the posterior tibial vessels and nerve, and the peroneal vessels; by its *deep surface*, with the interosseous ligament, the tibia, fibula, and ankle-joint.

Nerves.—The Popliteus is supplied by the fourth and fifth lumbar and first sacral nerves, through the internal popliteal; the Flexor longus digitorum and Tibialis posticus by the fifth lumbar and first and second sacral; and the Flexor longus hallucis by the fifth lumbar and first and second sacral nerves through the posterior tibial.

Actions.—The Popliteus assists in flexing the leg upon the thigh; when the leg is flexed, it will rotate the tibia inward. It is especially called into action at the commencement of the act of bending the knee, inasmuch as it produces a slight inward rotation of the tibia, which is essential in the early stages of this movement. The Tibialis posticus is a direct Extensor of the foot at the ankle-joint; acting in conjunction with the Tibialis anticus, it turns the sole of the foot inward (*i. e.*, inverts the foot), antagonizing the Peronei, which turn it outward (evert it). In the sole of the foot the tendon of the Tibialis posticus lies directly below the inferior calcaneoscaphoid ligament, and is therefore an important factor in maintaining the arch of the foot. The Flexor longus digitorum and Flexor longus hallucis are the direct Flexors of the phalanges, and, continuing their action, extend the foot upon the leg; they assist the Gastrocnemius and Soleus in extending the foot, as in the act of walking or in standing on tiptoe. In consequence of the oblique direction of the tendon of the long Flexor, the toes would be drawn inward were it not for the Flexor accessorius muscle, which is inserted into the outer side of its tendon and draws

¹ That is, in the order of dissection of the sole of the foot.

it to the middle line of the foot during its action. Taking their fixed point from the foot, these muscles serve to maintain the upright posture by steadying the tibia and fibula perpendicularly upon the ankle-joint. They also serve to raise these bones from the oblique position they assume in the stooping posture.

7. The Fibular Region (Fig. 383).

Peroneus longus.

Peroneus brevis.

Dissection.—The muscles are readily exposed by removing the fascia covering their surface, from below upward, in the line of direction of their fibres.

The **Peroneus longus** (*m. peronæus longus*) is situated at the upper part of the outer side of the leg, and is the more superficial of the two muscles. It *arises* from the head and upper two-thirds of the outer surface of the shaft of the fibula, from the deep surface of the fascia, and from the intermuscular septa between it and the muscles on the front, and those on the back of the leg, occasionally also by a few fibres from the outer tuberosity of the tibia. Between its attachment to the head and to the shaft of the fibula there is a small interval of bone from which no muscle fibres arise; through this gap the external popliteal nerve passes beneath the muscle. The muscle terminates in a long tendon, which passes behind the outer malleolus, in a groove common to it and the tendon of the Peroneus brevis, behind which it lies, the groove being converted into a canal by a fibrous band, and the tendons being invested by a common synovial membrane; it is then reflected obliquely forward across the outer side of the os calcis, below its peroneal tubercle, being contained in a separate fibrous sheath, lined by a prolongation of the synovial membrane which lines the groove behind the malleolus. Having reached the outer side of the cuboid bone, it runs in a groove on the under surface of that bone, which is converted into a canal by the long calcaneocuboid ligament, and is lined by a synovial membrane; the tendon then crosses the sole of the foot obliquely, and is *inserted* into the outer side of the base of the metatarsal bone of the great toe and the internal cuneiform bone (Figs. 399 and 300). Occasionally it sends a slip to the base of the second metatarsal bone. The tendon changes its direction at two points—first, behind the external malleolus; secondly, on the outer side of the cuboid bone; in both of these situations the tendon is thickened, and in the latter a sesamoid fibrocartilage, or sometimes a bone, is usually developed in its substance.

Relations.—By its *superficial surface*, with the fascia and integument; by its *deep surface*, with the fibula, external popliteal nerve, the Peroneus brevis, os calcis, and cuboid bone; by its *anterior border*, with an intermuscular septum, which intervenes between it and the Extensor longus digitorum; by its *posterior border*, with an intermuscular septum, which separates it from the Soleus above and the Flexor longus hallucis below.

The **Peroneus brevis** (*m. peronæus brevis*) lies beneath the Peroneus longus, and is shorter and smaller than it. It *arises* from the lower two-thirds of the external surface of the shaft of the fibula, internal to the Peroneus longus, and from the intermuscular septa separating it from the adjacent muscles on the front and back part of the leg. The fibres pass vertically downward, and terminate in a tendon which runs in front of that of the preceding muscle through the same groove, behind the external malleolus, being contained in the same fibrous sheath and lubricated by the same synovial membrane. It then passes through a separate sheath on the outer side of the os calcis, above that for the tendon of the Peroneus longus, the two tendons being here separated by the peroneal tubercle, and is finally *inserted* into the tuberosity at the base of the metatarsal bone of the little toe, on its outer side.

Relations.—By its *superficial surface*, with the Peroneus longus and the fascia of the leg and foot; by its *deep surface*, with the fibula and outer side of the os calcis.

Nerves.—The Peroneus longus and brevis are supplied by the fourth and fifth lumbar and first sacral nerves through the musculocutaneous branch of the external popliteal nerve.

Actions.—The Peroneus longus and brevis extend the foot upon the leg, in conjunction with the Tibialis posticus, antagonizing the Tibialis anticus and Peroneus tertius, which are Flexors of the foot. The Peroneus longus also everts the sole of the foot; hence, the extreme eversion occasionally observed in fracture of the lower end of the fibula, where that bone offers no resistance to the action of this muscle. From the oblique direction of the Peroneus longus tendon across the sole of the foot it is an important agent in the maintenance of the transverse arch of the foot. Taking their fixed point below, the Peronei serve to steady the leg upon the foot. This is especially the case when standing upon one leg, when the tendency of the superincumbent weight is to throw the leg inward; the Peroneus longus overcomes this tendency by drawing on the outer side of the leg, and thus maintains the perpendicular direction of the limb.

Applied Anatomy.—The student should now consider the position of the tendons of the various muscles of the leg, their relation with the ankle-joint and surrounding bloodvessels, and especially their action upon the foot, as their rigidity and contraction give rise to one or other of the kinds of deformity known as club-foot. The most simple and common deformity, and one that is rarely, if ever, congenital, is the *talipes equinus*, the heel being raised by rigidity and contraction of the Gastrocnemius muscle, and the patient walking upon the ball of the foot. In the *talipes varus* the foot is forcibly adducted and the inner side of the sole raised, sometimes to a right angle with the ground, by the action of the Tibialis anticus and posticus. In the *talipes valgus* the outer edge of the foot is raised by the Peronei muscles, and the patient walks on the inner ankle. In the *talipes calcaneus* the toes are raised by the Extensor muscles, the heel is depressed, and the patient walks upon it. Other varieties of deformity are met with, as the *talipes equinovarus*, *equinovalgus*, and *calcaneovalgus*, whose names sufficiently indicate their nature. Of these, the talipes equinovarus is the most common congenital form; the heel is raised by the tendo Achillis, the inner border of the foot drawn upward by the Tibialis anticus, the anterior two-thirds twisted inward by the Tibialis posticus, and the arch increased by the contraction of the plantar fascia, so that the patient walks on the middle of the outer border of the foot. Each of these deformities may sometimes be successfully relieved by division of the opposing tendons and fascia; by this means the foot regains its proper position, and the tendons subsequently heal. The operation is easily performed by putting the contracted tendon upon the stretch, and dividing it by means of a narrow, sharp-pointed knife inserted beneath it. *Pes cavus*, or hollow foot, is accentuation of the longitudinal arch. *Pes planus*, or flat-foot, has been discussed on page 349.

Rupture of a few of the fibres of the Gastrocnemius may take place. *Rupture of the Plantaris tendon* not uncommonly occurs, especially in men somewhat advanced in life, from some sudden exertion, and frequently occurs during the game of lawn tennis, and is hence known as *lawn-tennis leg*. The accident is accompanied by a sudden pain, and produces a sensation as if the individual had been struck a violent blow on the part. The tendo Achillis is also sometimes ruptured. It is stated that John Hunter ruptured his tendo Achillis while dancing at the age of forty. The bursa interposed between the posterior surface of the os calcis and the tendo Achillis, just above the point of insertion of the tendon, may become inflamed, producing a disabling pain (*achillodynia*, or *Albert's disease*).

V. MUSCLES AND FASCIA OF THE FOOT.

The fibrous bands, or thickened portions of the fascia of the leg, which bind down the tendons in front of and behind the ankle in their passage to the foot, are termed the annular ligaments, and are three in number—**anterior**, **internal**, and **external**.

The **Anterior Annular Ligament** (Fig. 393) consists of a **superior** or **transverse portion** (*ligamentum transversum cruris*), which binds down the Extensor tendons as they descend on the front of the tibia and fibula; and an **inferior** or **Y-shaped portion** (*ligamentum cruciatum cruris*), which retains them in connection with the tarsus, the two portions being connected by a thin intervening layer of fascia. The transverse portion is attached externally to the lower end of the fibula and internally to the tibia; above it is continuous with the fascia of the leg; it contains only one synovial sheath, for the tendon of the Tibialis anticus; the other tendons and the anterior tibial vessels and nerve passing beneath it, but without any dis-

tinct synovial sheath. The Y-shaped portion is placed in front of the ankle-joint, the stem of the Y, the **fundiform ligament of Retzius**, being attached externally to the upper surface of the os calcis, in front of the depression for the interosseous ligament; it is directed inward, as a double layer, one lamina passing in front, and the other behind, the tendons of the Peroneus tertius and Extensor longus digitorum. At the inner border of the latter tendon these two layers join, forming a sheath in which the tendons are enclosed, surrounded by a synovial membrane. From the inner extremity of this sheath the two limbs of the Y diverge; one passes upward and inward, to be attached to the internal malleolus, passing over the Extensor proprius hallucis and the vessels and nerves, but enclosing the Tibialis anticus and its synovial sheath by a splitting of its fibres. The other limb extends downward and inward to be attached to the inner border of the plantar fascia, and passes over the tendons of the Extensor proprius hallucis and Tibialis anticus and also the vessels and nerves. These two tendons are contained in separate synovial sheaths situated beneath the ligament.

The **Internal Annular Ligament** (*ligamentum laciniatum*) is a strong fibrous band which extends from the inner malleolus above to the internal margin of the os calcis below, converting a series of grooves in this situation into canals for the passage of the tendons of the Flexor muscles and vessels into the sole of the foot. It is continuous by its upper border with the deep fascia of the leg, and by its lower border with the plantar fascia and the fibres of origin of the Abductor hallucis muscle. The four canals which the ligament completes transmit, counting from before backward, *first*, the tendon of the Tibialis posticus; *second*, the tendon of the Flexor longus digitorum; *third*, the posterior tibial vessels and nerve, which run through a broad space beneath the ligament; *lastly*, in a canal formed partly by the astragalus, the tendon of the Flexor longus hallucis. The canals for the tendons are lined by a separate synovial membrane.

The **External Annular Ligament** is divided into two portions—a **superior portion** (*retinaculum mm. peronaeorum superius*), which extends from the extremity of the outer malleolus to the outer surface of the os calcis; it binds down the tendons of the Peroneus longus and brevis muscles in their passage behind the external malleolus. The two tendons are enclosed in one synovial sac. An **inferior portion** (*retinaculum mm. peronaeorum inferius*), which bridges the Peronei on the side of the os calcis and is attached to the bone above and below them.

8. The Dorsal Region (Fig. 393).

Extensor brevis digitorum.

Fascia (*fascia dorsalis pedis*).—The fascia on the dorsum of the foot is a thin membranous layer continuous above with the anterior margin of the annular ligament; it becomes gradually lost opposite the heads of the metatarsal bones, and on each side blends with the lateral portions of the plantar fascia; it forms a sheath for the tendons placed on the dorsum of the foot. On the removal of this fascia the muscle and tendons of the dorsal region of the foot are exposed.

The **Extensor brevis digitorum** (*m. extensor digitorum brevis*) (Fig. 393) is a broad thin muscle which *arises* from the fore part of the upper and outer surfaces of the os calcis, in front of the groove for the Peroneus brevis, from the external calcaneo-astragaloid ligament, and from the common limb of the Y-shaped portion of the anterior annular ligament. It passes obliquely across the dorsum of the foot, and terminates in four tendons. The innermost, which is the largest, is *inserted* into the dorsal surface of the base of the first phalanx of the great toe, crossing the dorsalis pedis artery; the other three, into the outer sides of the long Extensor tendons of the second, third, and fourth toes.

Nerves.—It is supplied by the anterior tibial nerve.

Actions.—The Extensor brevis digitorum is an accessory to the long Extensor, extending the phalanges of the four inner toes, but acting only on the first phalanx of the great toe. The obliquity of its direction counteracts the oblique movement given to the toes by the long Extensor, so that, both muscles acting together, the toes are evenly extended.

9. The Plantar Region (Figs. 398, 399).

The **plantar fascia** (*aponeurosis plantaris*), the densest of all the fibrous membranes, is of great strength, and consists of pearly white glistening fibres, disposed, for the most part, longitudinally; it is divided into a central and two lateral portions.

The **central portion**, the thickest, is narrow behind and *attached* to the inner tubercle of the os calcis, posterior to the origin of the Flexor brevis digitorum, and, becoming broader and thinner in front, divides near the heads of the metatarsal bones into five processes, one for each of the toes. Each of these processes divides opposite the metatarsophalangeal articulation into two strata, superficial and deep. The superficial stratum is *inserted* into the skin of the transverse sulcus which divides the toes from the sole. The deeper stratum divides into two slips which embrace the sides of the Flexor tendons of the toes, and blend with the sheaths of the tendons, and laterally with the transverse metatarsal ligament, thus forming a series of arches through which the tendons of the short and long Flexors pass to the toes. The intervals left between the five processes allow the digital vessels and nerves and the tendons of the Lumbricales muscles to become superficial. At the point of division of the fascia into processes and slips numerous transverse fibres are superadded, which serve to increase the strength of the fascia at this part by binding the processes together and connecting them with the integument. The central portion of the plantar fascia is continuous with the lateral portions at each side, and from its deep surface sends upward two strong vertical intermuscular septa, which separate the middle from the external and internal groups of plantar muscles; from these, again, thinner transverse septa are derived, which separate the various layers of muscles in this region. The deep surface of this fascia gives attachment behind to the Flexor brevis digitorum muscle.

The **lateral portions** of the plantar fascia are thinner than the central division, and cover the sides of the foot. The **outer portion** covers the under surface of the Abductor minimi digiti; it is thick behind, thin in front, and extends from the os calcis to the base of the fifth metatarsal bone, to the outer side of which it is attached; it is continuous internally with the central portion of the plantar fascia, and externally with the dorsal fascia. The **inner portion** is very thin, and covers the Abductor hallucis muscle; it is attached to the internal annular ligament, and is continuous around the side of the foot with the dorsal fascia, and externally with the middle portion of the plantar fascia.

The muscles in the plantar region of the foot may be divided into three groups, in a similar manner to those in the hand: (1) Those of the internal plantar region are connected with the great toe, and correspond with those of the thumb; (2) those of the external plantar region are connected with the little toe, and correspond with those of the little finger; and (3) those of the middle plantar region are connected with the tendons intervening between the two former groups. But in order to facilitate the dissection of these muscles it will be found more convenient to divide them into four layers, as they present themselves, in the order in which they are successively exposed.

The First Layer.

Abductor hallucis.

Flexor brevis digitorum.

Abductor minimi digiti.

Dissection.—Remove the fascia on the inner and outer sides of the foot, commencing in front over the tendons and proceeding backward. The central portion should be divided transversely in the middle of the foot, and the two flaps dissected forward and backward.

The **Abductor hallucis** (*m. abductor hallucis*) lies along the inner border of the foot and covers the first parts of the plantar vessels and nerves. It *arises* from the inner tubercle on the under surface of the os calcis; from the internal annular ligament; from the plantar fascia; and from the intermuscular septum between it and the Flexor brevis digitorum. The fibres terminate in a tendon which is *inserted*, together with the innermost tendon of the Flexor brevis hallucis, into the inner side of the first phalanx of the great toe.

The **Flexor brevis digitorum** (*m. flexor digitorum brevis*) lies in the middle of the sole of the foot, immediately beneath the plantar fascia, with which it is firmly united. Its deep surface is separated from the external plantar vessels and nerves by a thin layer of fascia. It *arises* by a narrow tendinous process, from the inner tubercle of the os calcis, from the central part of the plantar fascia, and from the intermuscular septa between it and the adjacent muscles. It passes forward, and divides into four tendons, one for each of the four outer toes. Opposite the bases of the first phalanges each tendon divides into two slips, to allow of the passage of the corresponding tendon of the Flexor longus digitorum; the two portions of the tendon then unite and form a grooved channel for the reception of the accompanying long Flexor tendon. Finally, they divide a second time, to be *inserted* into the middle of the sides of the second phalanges. The mode of division of the tendons of the Flexor brevis digitorum and their insertion into the phalanges is analogous to the division and insertion of the Flexor sublimis digitorum in the hand.

FIG. 398.—Muscles of the sole of the foot.
First layer.

Fibrous Sheaths of the Flexor Tendons.—These are not so well marked as in the fingers. The Flexor tendons of the toes as they run along the phalanges are retained against the bones by a fibrous sheath, forming osseaponeurotic canals. These sheaths are formed by strong fibrous bands which arch across the tendons

¹ That is, in order of dissection of the sole of the foot.

and are attached on each side to the margins of the phalanges. Opposite the middle of the proximal and second phalanges the sheath is very strong, and the fibres pass transversely, but opposite the joints it is much thinner, and the fibres pass obliquely. Each sheath is lined by a synovial membrane which is reflected upon the contained tendon.

The **Abductor minimi digiti** (*m. abductor digiti quinti*) lies along the outer border of the foot, and is in relation by its inner margin with the external plantar vessels and nerves. It *arises*, by a very broad origin, from the outer tubercle of the os calcis, from the under surface of the os calcis between the two tubercles, from the fore part of the inner tubercle, from the plantar fascia and the intermuscular septum, between it and the Flexor brevis digitorum. Its tendon, after gliding over a smooth facet on the under surface of the base of the fifth metatarsal bone, is *inserted* with the short Flexor of the little toe into the outer side of the base of the first phalanx of this toe.

Dissection.—The muscles of the superficial layer should be divided at their origin by inserting the knife beneath each, and cutting obliquely backward, so as to detach them from the bone; they should then be drawn forward, in order to expose the second layer, but not cut away at their insertion. The two layers are separated by a thin membrane, the *deep plantar fascia*, on the removal of which is seen the tendon of the Flexor longus digitorum, the Flexor accessorius, the tendon of the Flexor longus hallucis, and the Lumbricales. The long Flexor tendons diverge from each other at an acute angle; the Flexor longus hallucis runs along the inner side of the foot, on a plane superior to that of the Flexor longus digitorum, the direction of the latter being obliquely outward.

The Second Layer.

Flexor accessorius.

Lumbricales.

The **Flexor accessorius** (*m. quadratus plantae*) is separated from the muscles of the first layer by the external plantar vessels and nerves. It *arises* by two heads, which are separated from each other by the long plantar ligament; the **inner** or **larger head**, which is muscular, *arises* from the inner concave surface of the os calcis below the groove which lodges the tendon of the Flexor longus digitorum; the **outer head**, flat and tendinous, *arises* from the outer surface of the os calcis, in front of its lesser tubercle, and from the long plantar ligament; the two portions join at an acute angle, and are *inserted* into the outer margin and upper and under surfaces of the tendon of the Flexor longus digitorum, forming a kind of groove in which the tendon is lodged.¹

The **Lumbricales** (*m. lumbricales*) are four small muscles accessory to the tendons of the Flexor longus digitorum; they *arise* from the tendons of the long Flexor, as far back as their angle of division, each arising from two tendons, except the internal one. Each muscle terminates in a tendon, which passes forward on the inner side of the four lesser toes and is *inserted* into the expansion of the long Extensor tendon on the dorsum of the first phalanx of the corresponding toe.

Dissection.—The Flexor tendons should be divided at the back part of the foot, and the Flexor accessorius at its origin, and drawn forward, in order to expose the third layer.

The Third Layer.

Flexor brevis hallucis.

Flexor brevis minimi digiti.

Adductor obliquus hallucis.

Adductor transversus hallucis.

The **Flexor brevis hallucis** (*m. flexor hallucis brevis*) *arises*, by a pointed tendinous process, from the inner part of the under surface of the cuboid bone,

¹ According to Turner, the fibres of the Flexor accessorius end in aponeurotic bands, which contribute slips to the second, third, and fourth digits.

from the contiguous portion of the external cuneiform, and from the prolongation of the tendon of the *Tibialis posticus*, which is attached to that bone. The muscle divides in front into two portions which are *inserted* into the inner and outer sides of the base of the first phalanx of the great toe, a sesamoid bone being developed in each tendon at its insertion. The **inner portion** of this muscle is blended with

FIG. 399.—Muscles of the sole of the right foot.
Second layer.

FIG. 400.—Muscles of the sole of the right foot.
Third layer.

the *Abductor hallucis* previous to its insertion, the **outer portion** with the *Adductor obliquus hallucis*, and the tendon of the *Flexor longus hallucis* lies in a groove between them.

The **Adductor obliquus hallucis** (*caput obliquum m. adductoris hallucis*) is a large, thick, fleshy mass passing obliquely across the foot and occupying the hollow space between the four inner metatarsal bones. It *arises* from the tarsal extremities of the second, third, and fourth metatarsal bones, and from the sheath of the tendon of the *Peroneus longus*, and is *inserted*, together with the outer portion of the *Flexor brevis hallucis*, into the outer side of the base of the first phalanx of the great toe.

The small muscles of the great toe, the Abductor, Flexor brevis, Adductor obliquus, and Adductor transversus, like the similar muscles of the thumb, give off fibrous expansions, at their insertions, to blend with the long Extensor tendon.

The **Adductor transversus hallucis** (*caput transversum m. adductoris hallucis*) is a narrow, flat, muscular fasciculus, stretched transversely across the heads of the metatarsal bones, between them and the Flexor tendons. It *arises* from the inferior metatarsophalangeal ligaments of the three outer toes, sometimes only from the third and fourth and from the transverse ligament of the metatarsus; and is inserted into the outer side of the first phalanx of the great toe, its fibres being blended with the tendon of insertion of the Adductor obliquus hallucis.

The **Flexor brevis minimi digiti** (*m. flexor digiti quinti brevis*) lies on the metatarsal bone of the little toe, and much resembles one of the Interossei. It *arises* from the base of the metatarsal bone of the little toe, and from the sheath of the Peroneus longus; its tendon is *inserted* into the base of the first phalanx of the little toe on its outer side. Occasionally some of the deeper fibres of the muscle are inserted into the outer part of the distal half of the fifth metatarsal bone; these are described by some as a distinct muscle, the **Opponens minimi digiti**.

The Fourth Layer.

The Interossei.

The **Interossei muscles** (*mm. interossei*) in the foot are similar to those in the hand, with this exception, that they are grouped around the middle line of the *second* digit, instead of the middle line of the *third* digit, as in the hand. They are *seven* in number, and consists of two groups, Dorsal and Plantar.

FIG. 401.—The Dorsal interossei. Left foot. The line marked by an * is that from which abduction is performed.

FIG. 402.—The Plantar interossei. Left foot. The line marked by an * is that to which adduction is made.

The **Dorsal Interossei** (*m. interossei dorsales*), *four* in number, are situated between the metatarsal bones. They are bipenniform muscles, *arising* by two heads

from the adjacent sides of the metatarsal bones, between which they are placed; their tendons are *inserted* into the bases of the first phalanges, and into the aponeurosis of the corresponding slip of the common Extensor tendon. In the angular interval left between the heads of each muscle at its posterior extremity the perforating arteries pass to the dorsum of the foot, except in the First interosseous muscle, where the interval allows the passage of the communicating branch of the dorsalis pedis artery. The First dorsal interosseous muscle is *inserted* into the inner side of the second toe; the other three are *inserted* into the outer sides of the second, third, and fourth toes.

The **Plantar Interossei** (*m. interossei plantares*), three in number, lie beneath, rather than between, the metatarsal bones. They are single muscles, and each arises from but one metatarsal bone. They *arise* from the base and inner sides of the shaft of the third, fourth, and fifth metatarsal bones, and are *inserted* into the inner sides of the bases of the first phalanges of the same toes, and into the aponeurosis of the corresponding slip of the common Extensor tendon.

Nerves.—The Flexor brevis digitorum, the Flexor brevis and Abductor hallucis, and the innermost Lumbrical are supplied by the medial plantar nerve. All the other muscles in the sole of the foot by the lateral plantar. The First dorsal interosseous muscle frequently receives an extra filament from the internal branch of the anterior tibial nerve on the dorsum of the foot, and the Second dorsal interosseous a twig from the external branch of the same nerve.

Actions.—All the muscles of the foot act upon the toes, and for purposes of description as regard their action may be grouped as Abductors, Adductors, Flexors, or Extensors. The *Abductors* are the Dorsal interossei, the Abductor hallucis, and the Abductor minimi digiti. The Dorsal interossei are Abductors from an imaginary line passing through the axis of the second toe, so that the first muscle draws the second toe inward, toward the great toe; the second muscle draws the same toe outward; the third draws the third toe, and the fourth draws the fourth toe, in the same direction. Like the Interossei in the hand, they also help to flex the proximal phalanges and to extend the two terminal phalanges. The Abductor hallucis abducts the great toe from the others, and also flexes the proximal phalanx of this toe. And in the same way the action of the Abductor minimi digiti is twofold—as an Abductor of this toe from the others, and also as a Flexor of the proximal phalanx. The *Adductors* are the Plantar interossei, the Adductor obliquus hallucis, and the Adductor transversus hallucis. The Plantar interosseous muscles adduct the third, fourth, and fifth toes toward the imaginary line passing through the second toe, and by means of their insertion into the aponeurosis of the Extensor tendon they, with the Dorsal interossei, flex the proximal phalanges and extend the two terminal phalanges. The Adductor obliquus hallucis is chiefly concerned in adducting the great toe toward the second one, but also assists in flexing this toe. The Adductor transversus hallucis approximates all the toes, and thus increases the curve of the transverse arch of the metatarsus. The *Flexors* are the Flexor brevis digitorum, the Flexor accessorius, the Flexor brevis hallucis, the Flexor brevis minimi digiti, and the Lumbricales. The Flexor brevis digitorum flexes the second phalanges upon the first, and, continuing its action, may flex the first phalanges also and bring the toes together. The Flexor accessorius assists the long Flexor of the toes, and converts the oblique pull of the tendons of that muscle into a direct backward pull upon the toes. The Flexor brevis hallucis flexes and slightly adducts the first phalanx of the great toe. The Flexor brevis minimi digiti flexes the little toe and draws its metatarsal bone downward and inward. The Lumbricales, like the corresponding muscles in the hand, assist in flexing the proximal phalanx, and by their insertion into the long Extensor tendon aid in straightening the two terminal phalanges. The only muscle in the *Extensor* group is the Extensor brevis digitorum. It extends the first phalanx of the great toe, and assists the long Extensor in extending the next three toes, and at the same time gives to the toes an outward direction when they are extended.

SURFACE FORM OF THE LOWER EXTREMITY.

Of the muscles of the thigh, those of the iliac region have no influence on surface form, while those of the anterior femoral region, being to a great extent superficial, largely contribute to the surface form of this part of the body. The **Tensor fasciæ femoris** produces a broad elevation immediately below the anterior portion of the crest of the ilium and behind the anterior superior spinous process. From its lower border a longitudinal groove, corresponding to the ilio-tibial band, may be seen running down the outer side of the thigh to the outer side of the knee-joint. The **Sartorius** muscle, when it is brought into action by flexing the leg on the thigh

and the thigh on the pelvis, and rotating the thigh outward, presents a well-marked surface form. At its upper part, where it constitutes the outer boundary of Scarpa's triangle, it forms a prominent oblique ridge, which becomes changed into a flattened plane below, and this gradually merges in a general fullness on the inner side of the knee-joint. When the Sartorius is not in action, a depression exists between the **Quadriceps extensor** and the Adductor muscles, running obliquely downward and inward from the apex of Scarpa's triangle to the inner side of the knee, which depression corresponds to this muscle. In the depressed angle formed by the divergence of the Sartorius and Tensor fasciae femoris muscles, just below the anterior superior spinous process of the ilium, the **Rectus femoris** muscle appears, and, below this, determines to a great extent the convex form of the front of the thigh. In a well-developed subject the borders of the muscle, when in action, are clearly to be defined. The **Vastus externus** forms a long flattened plane on the outer side of the thigh, traversed by the longitudinal groove formed by the iliotibial band. The **Vastus internus**, on the inner side of the lower half of the thigh, gives rise to a considerable prominence, which increases toward the knee and terminates somewhat abruptly in this situation with a full, curved outline. The **Crureus** and **Subcrureus** are completely hidden, and do not directly influence surface form. The Adductor muscles, constituting the internal femoral group, are not to be individually distinguished from each other, with the exception of the upper tendon of the Adductor longus and the lower tendon of the Adductor magnus. The upper tendon of the **Adductor longus**, when the muscle is in action, stands out as a prominent ridge, which runs obliquely downward and outward from the neighborhood of the pubic spine, and forms the inner boundary of a flattened triangular space on the upper part of the front of the thigh, known as Scarpa's triangle. The lower tendon of the **Adductor magnus** can be distinctly felt as a short ridge extending down to the Adductor tubercle on the internal condyle, between the Sartorius and Vastus internus. The Adductor group of muscles fills in the triangular space at the upper part of the thigh, formed between the oblique femur and the pelvic wall, and to them is due the contour of the inner border of the thigh, the **Gracilis** largely contributing to the smoothness of the outline. These muscles are not marked off on the surface from those of the posterior femoral region by any intermuscular marking, but on the outer side of the thigh these latter muscles are defined from the Vastus externus by a distinct marking, corresponding to the external intermuscular septum. The **Gluteus maximus** and a part of the **Gluteus medius** are the only muscles of the buttock which influence surface form. The other part of the Gluteus medius, the Gluteus minimus, and the external Rotators are completely hidden. The Gluteus maximus forms the full rounded outline of the buttock; it is more prominent behind, compressed in front, and terminates at its tendinous insertion in a depression immediately behind the great trochanter. Its lower border does not correspond to the gluteal fold, but is much more oblique, being marked by a line drawn from the side of the coccyx to the junction of the upper with the lower two-thirds of the thigh on the outer side. From beneath the lower margin of this muscle the *Hamstring muscles* appear, at first narrow and not well marked, but as they descend becoming more prominent and widened out, and eventually dividing into two well-marked ridges, which constitute the upper boundaries of the popliteal space, and are formed by the tendons of the inner and outer Hamstring muscles, respectively. In the upper part of the thigh these muscles are not to be individually distinguished from each other, but lower down the separation between the Semitendinosus and Semimembranosus is denoted by a slight intermuscular marking. The external hamstring tendon, formed by the **Biceps** is seen as a thick cord running down to the head of the fibula. The inner Hamstring tendons comprise the Semitendinosus, the Semimembranosus, and the Gracilis. The **Semitendinosus** is the most internal of these, and can be felt, in certain positions of the limb, as a sharp cord; the **Semimembranosus** is thick, and the Gracilis is situated a little farther forward than the other two. All the muscles on the front of the leg appear to a certain extent somewhere on the surface, but the form of this region is mainly dependent upon the Tibialis anticus and the Extensor longus digitorum. The **Tibialis anticus** is well marked, and presents a fusiform enlargement at the outer side of the tibia, and projects beyond the crest of the shin bone. From the muscular mass its tendons may be traced downward, standing out boldly, when the muscle is in action, on the front of the tibia and ankle-joint, and coursing down to its insertion along the inner border of the foot. A well-marked groove separates this muscle externally from the **Extensor longus digitorum**, which fills up the rest of the space between the upper part of the shaft of the tibia and fibula. It does not present so bold an outline as the Tibialis anticus, and its tendon below, diverging from the tendon of the Tibialis anticus, forms with the latter a sort of plane, in which may be seen the tendon of the Extensor proprius hallucis. A groove on the outer side of the Extensor longus digitorum, seen most plainly when the muscle is in action, separates the tendon from a slight eminence corresponding to the **Peroneus tertius**. The fleshy fibres of the **Peroneus longus** are strongly marked at the upper part of the outer side of the leg, especially when the muscle is in action. It forms a bold swelling, separated by furrows from the Extensor longus digitorum in front and the Soleus behind. Below, the fleshy fibres terminate abruptly in a tendon which overlaps the more flattened form of the **Peroneus brevis**. At the external malleolus the tendon of the Peroneus brevis is more marked than that

of the *Peroneus longus*. On the dorsum of the foot the tendons of the *Extensor* muscles, emerging from beneath the anterior annular ligament, spread out and can be distinguished in the following order: The most internal and largest is the *Tibialis anticus*, then the *Extensor proprius hallucis*; next comes the *Extensor longus digitorum*, dividing into four tendons to the four outer toes; and lastly, most externally, is the *Peroneus tertius*. The flattened form of the dorsum of the foot is relieved by the rounded outline of the fleshy belly of the *Extensor brevis digitorum*, which forms a soft fulness on the outer side of the tarsus in front of the external malleolus, and by the Dorsal interossei, which bulge between the metatarsal bones. At the back of the knee is the popliteal space, bounded above by the tendons of the Hamstring muscle; below, by the two heads of the *Gastrocnemius*. Below this space is the prominent fleshy mass of the calf of the leg, produced by the *Gastrocnemius* and *Soleus*. When these muscles are in action, as in standing on tiptoe, the borders of the *Gastrocnemius* are well defined, presenting two curved lines, which converge to the tendon of insertion. Of these borders, the inner is more prominent than the outer. The fleshy mass of the calf terminates somewhat abruptly below in the tendo Achillis, which stands out prominently on the lower part of the back of the leg. It presents a somewhat tapering form in the upper three-fourths of its extent, but widens out slightly below. When the muscles of the calf are in action, the lateral portions of the *Soleus* may be seen, forming curved eminences, of which the outer is the longer, on either side of the *Gastrocnemius*. Behind the inner border of the lower part of the shaft of the tibia a well-marked ridge, produced by the tendon of the *Tibialis posticus*, is visible when this muscle is in a state of contraction. On the sole of the foot the superficial layer of muscles influences surface form; the *Abductor minimi digiti* most markedly. This muscle forms a narrow rounded elevation along the outer border of the foot, while the *Abductor hallucis* does the same, though to a less extent, on the inner side. The *Flexor brevis digitorum*, bound down by the plantar fascia, is not very apparent; it produces a flattened form, covered by the thickened skin of the sole, which is here thrown into numerous wrinkles.

APPLIED ANATOMY OF THE LOWER EXTREMITY.

The student should now consider the effects produced by the action of the various muscles in fractures of the bones of the lower extremity. The more common forms of fractures are selected for illustration and description.

FIG. 403.—Fracture of the neck of the femur within the capsular ligament.

In fracture of the neck of the femur internal to the capsular ligament (Fig. 403) the characteristic marks are slight shortening of the limb and eversion of the foot, neither of which symptoms occurs, however, in certain cases until some time after the injury. The eversion is caused

by the weight of the limb rotating it outward. The shortening is produced by the action of the Glutei, and by the Rectus femoris in front and the Biceps, Semitendinosus, and Semimembranosus behind.

In *fracture of the femur just below the trochanters* (Fig. 404) the upper fragment, the portion chiefly displaced, is tilted forward almost at right angles with the pelvis by the combined action of the Psoas and Iliacus, and, at the same time, everted and drawn outward by the external Rotator and Glutei muscles, causing a marked prominence at the upper and outer side of the thigh, and much pain from the bruising and laceration of the muscles. The limb is shortened, in consequence of the lower fragment being drawn upward by the Rectus in front, and the Biceps, Semimembranosus, and Semitendinosus behind, and is at the same time everted. This fracture may be reduced by direct relaxation of all the opposing muscles, to effect which the limb should be put up in such a manner that the thigh is flexed on the pelvis and the leg on the thigh.

FIG. 404.—Fracture of the femur below the trochanters.

FIG. 405.—Fracture of the femur above the condyles.

FIG. 406.—Fracture of the patella.

Oblique fracture of the femur immediately above the condyles (Fig. 405) is a formidable injury, and attended with considerable displacement. On examination of the limb the lower fragment may be felt deep in the popliteal space, being drawn backward by the Gastrocnemius and Plantaris muscles, and upward by the Hamstring and Rectus femoris muscles. The pointed end of the upper fragments is drawn inward by the Pectineus and Adductor muscles, and tilted forward by the Psoas and Iliacus, piercing the Rectus muscle and occasionally the integument. The greatest care is requisite in keeping the pointed extremity of the upper fragment in proper position; otherwise, after union of the fracture, the power of extension of the limb is partially destroyed from the Rectus femoris muscle being held down by the fractured end of the bone, and from the patella, when elevated, being drawn upward against the projecting fragment.

In *fracture of the patella* (Fig. 406) the fragments are separated by the effusion which takes place into the joint, and by the action of the Quadriceps extensor; the extent of separation of the two fragments depending upon the degree of laceration of the ligamentous structures around the bone.

The *tibia is fractured* most commonly by indirect force at the junction of the middle third with the lower third of the shaft. Compound fractures are more common in the leg than

in any other region of the body because the tibia is such a superficial bone and is so much exposed to injury. Most fractures from indirect force are oblique.

In *oblique fracture of the shaft of the tibia* (Fig. 407), if the fracture has taken place obliquely from above, downward and forward, the fragments override each other, the lower fragments being drawn backward and upward by the powerful action of the muscles of the calf; the pointed extremity of the upper fragment projects forward immediately beneath the integument, often protruding through it and rendering the fracture a compound one. If the direction of the fracture is the reverse of that shown in the figure, the pointed extremity of the lower fragment projects forward, riding upon the lower end of the upper one. By bending the knee, which relaxes the opposing muscles, and making extension from the ankle and counterextension at the knee, the fragments may be brought into apposition.

FIG. 407.—Oblique fracture of the shaft of the tibia.

FIG. 408.—Fracture of the fibula, with dislocation of the foot outward—"Pott's fracture."

Fracture of the fibula with dislocation of the foot outward (Fig. 408), commonly known as *Pott's fracture*, is one of the most frequent injuries of the ankle-joint. The fibula is fractured about three inches above the ankle; in addition to this the internal malleolus is broken off, or the deltoid ligament torn through, and the end of the tibia displaced from the corresponding surface of the astragalus. The foot is markedly everted, and the sharp edge of the upper end of the fractured malleolus presses strongly against the skin; at the same time, the heel is drawn up by the muscles of the calf. This injury can generally be reduced by flexing the leg at right angles with the thigh, which relaxes all the opposing muscles, and by making extension from the ankle and counterextension at the knee.

THE VASCULAR SYSTEMS.

THE vascular systems comprise the heart and bloodvessels (*blood-vascular system*) for the circulation of the blood, and the lymphatics and lacteals (*lymph-vascular system*), collecting the lymph from the tissues and the chyle from the digestive tract and conveying them to the great veins.

THE HEART AND BLOODVESSELS.

The heart is the central organ of the blood-vascular system, and consists of a hollow mass of muscle tissue; by its contraction the blood is pumped to all parts of the body through a complicated series of tubes, termed **arteries**. The arteries undergo enormous ramification in their course throughout the body, and end in very minute vessels, called **arterioles**, which, in their turn, open into a close-meshed network of microscopic vessels, termed **capillaries**. After the blood has passed through the capillaries it enters into minute vessels called **venules** and from them it is collected into a series of larger vessels, called **veins**, by which it is again returned to the heart. The passage of the blood through the heart and bloodvessels constitutes what is termed the **circulation of the blood**, of which the following is an outline: The human heart is divided by a septum into right and left halves, and each half is further separated into two cavities, termed the **auricle** and the **ventricle**. The heart, therefore, consists of *four* chambers, *two*, the right auricle and right ventricle, forming the right half, and *two*, the left auricle and left ventricle, forming the left half. The right half of the heart contains venous or deoxygenated blood; the left, arterial or pure blood. From the cavity of the left ventricle the aërated blood is carried into a large artery, the **aorta**, through the numerous branches of which it is distributed to all parts of the body, with the exception of the lungs. In its passage through the capillaries of the body the blood carries to the tissues the materials necessary for their growth and nourishment, and at the same time receives from the tissues the waste products resulting from their metabolism. In doing so it becomes changed from arterial into venous

FIG. 409.—Diagram to show the course of the circulation of the blood. This diagram does not show that the liver also receives blood through the hepatic artery.

blood, which is collected by the veins and through them returned to the right auricle of the heart. From this cavity the deoxygenated blood passes into the right ventricle, from which it is conveyed through the **pulmonary arteries** to the lungs. In the capillaries of the lungs it again becomes arterialized, and is then carried to the left auricle by the **pulmonary veins**. From this cavity it passes into that of the left ventricle, from which the cycle once more begins.

The course of the blood from the left ventricle through the body generally to the right side of the heart constitutes the greater or **systemic circulation**, while its passage from the right ventricle through the lungs to the left side of the heart is termed the lesser or **pulmonary circulation**.

FIG. 410.—Front view of the thorax, showing relation of the heart, lungs, etc., to the ribs and sternum. P. Pulmonary orifice. Ao. Aortic orifice. M. Left auriculoventricular orifice. Tr. Right auriculoventricular orifice.

It is necessary, however, to state that the blood which circulates through the spleen, pancreas, stomach, small intestine, and the greater part of the large intestine is not returned directly from these organs to the heart, but is collected into a large vein, termed the **portal vein**, by which it is carried to the liver. In the liver this vein divides, after the manner of an artery, and ultimately ends in capillary vessels, from which the rootlets of a series of veins, called the **hepatic veins**, arise; these carry the blood into the inferior vena cava (postcava), whence it is conveyed to the right auricle. From this it will be seen that the blood contained

in the portal vein passes through two sets of capillary vessels—(1) those in the spleen, pancreas, stomach, etc., and (2) those in the liver.

Speaking generally, the arteries may be said to contain pure and the veins impure blood. This is true of the systemic but not of the pulmonary vessels, since it has been seen that the impure blood is conveyed from the heart to the lungs by the pulmonary arteries, and the pure blood returned from the lungs to the heart by the pulmonary veins. Arteries, therefore, must be defined as vessels which convey blood *from* the heart, and veins as vessels which return blood *to* the heart.

The heart and lungs are contained within the cavity of the thorax, the walls of which afford them protection (Fig. 410). The heart lies between the two lungs, and is there enclosed within a seromembranous bag, the **pericardium**, while each lung is invested by a serous membrane, the **pleura**. The skeleton and cavity of the thorax were described on page 154.

FIG. 411.—Ligaments of the pericardium. (Modified from Teutleben.) Right lateral view, showing the right vertebropericardial ligaments, the right phrenopericardial, and the superior and inferior sternopericardial ligaments. (Poirier and Charpy.)

THE PERICARDIUM.

The **pericardium** (Figs. 411 and 412) is a conical seromembranous sac, placed in the middle mediastinum. In this sac the heart and the commencement of the great vessels are contained. It is placed behind the sternum and the cartilages

of the third, fourth, fifth, sixth, and seventh ribs of the left side, in the interval between the pleuræ. The apex of the sac is directed upward, while the base is applied to the central tendon of the Diaphragm.

In *front*, it is separated from the anterior wall of the thorax, in the greater part of its extent, by the lungs and pleuræ; but a small area, somewhat variable in size, and usually corresponding with the left half of the lower portion of the gladiolus of the sternum and the inner extremities of the cartilages of the fourth and fifth ribs of the left side, comes into direct relationship with the thoracic wall. The lower extremity of the thymus gland in the child is in contact with the front of the upper part of the pericardium. *Behind*, it rests upon the bronchi, the œsophagus, and the descending aorta. *Laterally*, it is covered by the pleuræ, and is in relation to the inner surface of the lungs; the phrenic nerve with its accompanying vessels descends between the pericardium and pleura on either side (Fig. 413).

FIG. 412.—The heart with part of the serous pericardium attached.

Structure of the Pericardium.—Although the pericardium is usually described as a single sac, an examination of its structure shows that it consists essentially of two sacs intimately connected with each other, but totally different in structure. The outer sac, known as the *fibrous pericardium*, consists of fibrous tissue. The inner sac, or *serous pericardium*, is composed of a delicate serous membrane which lies within the fibrous sac and lines its walls; the heart invaginates the wall of the serous sac from above and behind and practically obliterates its cavity, the space being a potential one, except in front, where a small interspace exists below the apex of the heart.

The *fibrous pericardium* forms a flask-shaped bag, the neck of which is closed by its fusion with the external coats of the great vessels, while its *base* is attached to the central tendon and to the muscle fibres of the left side of the Diaphragm. In some of the lower mammals the base is either completely separated from the Diaphragm or joined to it by some loose areolar

tissue; in man much of its diaphragmatic attachment consists of loose fibrous tissue which can be readily broken down, but over a small area the central tendon of the Diaphragm and the pericardium are completely fused. Above, the fibrous pericardium not only blends with the external coats of the great vessels, but is continuous with the pretracheal layer of the deep cervical fascia. By means of these upper and lower connections it is securely anchored within the thoracic cavity. It is also attached to the posterior surface of the sternum by two fibrous bands, the **superior** and **inferior sternopericardial ligaments** (*ligg. sternopericardiaca*); the upper passing to the manubrium, and the lower to the ensiform cartilage. On each side of the ascending aorta the pericardium sends upward a diverticulum; the one on the left side, somewhat conical in shape, passes upward and outward, between the arch of the aorta and the pulmonary artery, as far as the ductus arteriosus, where it terminates in a blind extremity, which is attached by loose connective tissue to this impervious duct (Fig. 411). The one on the right side passes upward and to the right, between the ascending aorta and superior vena cava (*precava*), and also terminates in a blind extremity.

FIG. 413.—Posterior wall of the pericardial sac, showing the lines of reflection of the serous pericardium on the great vessels.

The vessels receiving fibrous prolongations from this membrane are the aorta, the superior vena cava, the right and left pulmonary arteries, the four pulmonary veins, and the impervious ductus arteriosus. The inferior vena cava enters the pericardium through the central tendon of the Diaphragm, and consequently it receives no covering from the fibrous layer (Fig. 413).

The *serous pericardium* is, as already stated, a closed sac which lines the fibrous pericardium and is invaginated by the heart; it therefore consists of a *visceral* and a *parietal* portion. The visceral portion, or *epicardium*, covers the heart and the great vessels, and from the latter is continuous with the parietal layer which lines the fibrous pericardium. The portion which covers the vessels is arranged in the form of two tubes. The aorta and pulmonary artery are enclosed in one tube, the *arterial mesocardium*. The superior and inferior venæ cavæ and the four pulmonary veins are enclosed in a second tube, the *venous mesocardium*, the attachment

of which to the parietal layer presents the shape of an inverted Ω . The *cul-de-sac* enclosed between the limbs of the Ω is known as the **oblique sinus**, while the passage between the venous and arterial mesocardia—i. e., between the aorta and pulmonary artery in front and the auricles behind—is termed the **transverse sinus** (*sinus transversus pericardii*). The serous pericardium is smooth and glistening, and transudes a serous fluid, which serves to facilitate the movements of the heart.

The Vestigial Fold of the Pericardium.—Between the left pulmonary artery and subjacent pulmonary vein and behind the left extremity of the transverse sinus is a triangular fold of the serous pericardium; it is known as the **vestigial fold of Marshall** (*ligamentum v. cavae sinistrae*). It is formed by the duplicature of the serous layer over the remnant of the lower part of the **fetal left superior vena cava** (*v. cava sinistra*), or the **duct of Ouvier**, which becomes impervious after birth, and remains as a fibrous band stretching from the left superior intercostal vein to the left auricle, where it is continuous with a small vein, the **oblique vein of Marshall** (*v. obliqua atrii sinistri* [*Marshalli*]), which opens into the coronary sinus.

The **arteries** of the pericardium are derived from the internal mammary and its musculophrenic branch, and from the descending thoracic aorta.

The **nerves** of the pericardium are derived from the vagi, the phrenics, and the sympathetics.

Applied Anatomy.—The effusion of fluid into the pericardial sac often occurs in acute rheumatism or pneumonia, or in patients with chronic vascular and renal disease, embarrassing the heart's action and giving rise to signs of cardiac distress, such as pallor, a rapid and feeble pulse, dyspnea, and restlessness. On examination, the apical cardiac impulse is absent, or replaced by a more extensive indefinite and wavering pulsation; it may appear to be in the second, third, or fourth left space, and is then not an apex impulse, as Potain has stated, but due to the impact of some portion of the heart wall nearer its base. In children the precordial intercostal spaces may bulge outward. The most striking sign, however, is the great increase in all directions of the precordial dullness on percussion. This becomes pear-shaped, the stalk of the pear reaching up to about the left sternoclavicular articulation; the dullness also extends some distance to the right of the sternum, particularly in the fifth interspace (Rotch). The fluid collects mainly on either side of the heart, and below it, especially on the left side, where the Diaphragm can yield more readily to pressure than it can on the right. Ewart has drawn attention to the presence of a square patch of dullness over the base of the left lung behind, reaching up to the level of the ninth or tenth rib, and extending outward as far as the lower angle of the scapula; the underlying lung tissue gives the physical signs of compression or collapse.

Paracentesis of the pericardium is often required to relieve the urgent cardiac or respiratory distress in these cases, and should be performed without hesitation and before the patient is in *extremis*. It may also be required when the pericardium is filled with blood or pus, and as it is advisable to perform this operation without transfixing the pleura, the puncture should be made either in the fifth or sixth intercostal space on the left side and close to the sternum, so as to avoid wounding the internal mammary artery, which descends about half an inch from the sternal margin; or the needle may be entered at the left costoensiform angle and made to pass upward and backward behind the lower end of the body of the sternum into the pericardial sac. It must be remembered that even in the largest pericardial effusions, the heart itself lies almost in contact with the anterior wall of the thorax, and great care must be exercised to avoid piercing this organ.

Pericardiotomy is required when the effusion is of a purulent nature. In this operation a portion of the fifth or sixth costal cartilage is excised. An incision is made along the left border of the sternum from the upper border of the fourth cartilage to the seventh. Transverse incisions an inch long are then made outward from either extremity of this, and the rectangular flap thus formed reflected outward. The fifth costal cartilage is now separated from the sternum by means of a gouge, great care being taken not to let the instrument slip and penetrate too deeply. The cartilage is then seized with lion forceps and raised, the tissues beneath it being peeled off, so as to avoid wounding the internal mammary artery or the pleura. The *Triangularis sterni* is now scratched through with a director or the nail of the index finger close to the sternum, and the pericardium felt for and opened, the finger guarding the pleura and left internal mammary artery.

THE HEART (COR).

The **heart** is a hollow muscular organ of a conical form, placed between the lungs, and enclosed in the cavity of the pericardium.

Position (Fig. 414).—The heart is placed obliquely in the thorax behind the gladiolus and adjoining parts of the rib cartilages, and projects farther into the

left than into the right half of the thoracic cavity, so that about one-third of it is situated on the right and about two-thirds on the left of the mesal plane.

Size and Weight.—The normal heart, in the adult, measures five inches in length, three inches and a half in breadth at the broadest part, and two inches and a half in thickness. The prevalent weight, in the male, varies from ten to twelve ounces (average, eleven ounces); in the female, from eight to ten; its proportions to the body being as 1 to 160 in males; 1 to 150 in females. The heart continues to increase in weight and in size up to an advanced period of life; this increase is more marked in men than in women.

FIG. 414.—Position of the heart. The pericardium laid open. Adult male. (Poirier and Charpy.)

Configuration.—The heart is subdivided by a muscular septum into two lateral halves, which are named, respectively, the **right** or **pulmonary heart** and the **left** or **systemic heart**; and a transverse constriction subdivides each half of the organ into two cavities, the dorsal cavity on each side being called the **auricle**; the ventral, the **ventricle**. The heart, therefore, consists of *four* chambers—viz., the right and left auricles, and right and left ventricles. The course of the blood through the heart cavities and bloodvessels has already been described (page 549).

The division of the heart into four cavities is indicated upon its surface by grooves. The groove separating the auricles from the ventricles is called the

auriculoventricular groove (*sulcus coronarius*). It contains the trunks of the nutrient vessels of the heart, but is obliterated, in front, where it is crossed by the root of the pulmonary artery.

The **interauricular groove**, separating the two auricles, is scarcely marked on the postero-inferior aspect, while superiorly it is hidden by the pulmonary artery and aorta. The ventricles are separated by two furrows, the **interventricular grooves** (*sulci longitudinales*), one of which (*sulcus longitudinalis anterior*) is situated on the antero-superior surface close to the left margin of the heart, the other (*sulcus longitudinalis posterior*) on the postero-inferior surface near the right margin; these grooves extend from the base of the ventricular portion to a point a little to the right of the apex of the heart.

FIG. 415.—Base of the heart in place. The attachments of the pericardium are outlined in red. (Poirier and Charpy.)

The **base** (*basis cordis*) (Fig. 415), directed backward, a little upward, and to the right, is separated from the fifth, sixth, seventh, and eighth thoracic vertebræ by the œsophagus, aorta, and thoracic duct. It is formed mainly by the left auricle, and, to a small extent, by the back part of the right auricle. Somewhat quadrilateral in form, it is in relation *above* with the bifurcation of the pulmonary artery, and is bounded *below* by the posterior part of the auriculoventricular sulcus, containing the coronary sinus. On the *right* it is limited by the sulcus terminalis of the right auricle, and on the *left* by the vestigial fold and oblique vein of Marshall. The four pulmonary veins, two on either side, open into the left auricle, while the superior vena cava opens into the upper and the inferior vena cava into the lower part of the right auricle.

The **apex** (*apex cordis*) is directed downward, forward, and to the left, and is

overlapped by the left lung and pleura; it lies behind the fifth left intercostal space, three and a quarter inches (8 cm.) from the mid-sternal line, or about an inch and a half (4 cm.) below and three-quarters of an inch (2 cm.) to the inner side of the left nipple in the male. The apex is wholly made up of the left ventricle.

The **antero-superior surface** (*facies sternocostalis*) (Fig. 416) is directed forward, upward, and to the left. Its lower part is convex, formed chiefly by the right ventricle, and is traversed near its left margin by the anterior interventricular furrow. Its upper part is separated from the lower by the auriculoventricular groove; it is formed by the auricles, and presents a deep concavity (Fig. 416), occupied by the ascending aorta and the pulmonary artery.

FIG. 416.—Showing relations of opened heart to front of thorax.

The **postero-inferior surface** (*facies diaphragmatica*) (Fig. 416), which looks downward and slightly backward, is formed by the ventricles, and rests upon the central tendon and a small part of the left muscular portion of the Diaphragm. It is separated from the base by the posterior part of the auriculo-ventricular furrow, and is traversed obliquely by the posterior interventricular groove.

The **right margin** of the heart is long, and is formed by the right auricle above and the right ventricle below. The auricular portion is almost vertical, and is situated behind the third, fourth, and fifth right costal cartilages about 3 cm. from the middle line or half an inch from the margin of the sternum. The ventricular portion, thin and sharp, is named the *margo acutus*; it is nearly horizontal,

and extends from the sternal end of the sixth right costal cartilage behind the lower end of the gladiolus to the apex of the heart.

The **left margin**, or *margo obtusus*, is short, thick, and rounded; it is formed mainly by the left ventricle, but to a slight extent, above, by the left auricle. It extends from a point in the second left intercostal space, about 4.5 cm. from the mesal (middle) line, obliquely downward, with a convexity to the left, to the apex of the heart.

The Cavities of the Heart.—Each of the cavities of the heart is lined by the endocardium, a thin, smooth membrane which gives the glistening appearance to their internal surfaces and by reduplications forming the valves (mitral and tricuspid) guarding the orifices of communication and of the aorta and pulmonary artery.

The **Right Auricle**¹ (*atrium dextrum*) is the larger of the two auricles, although its walls are somewhat thinner than those of the left, measuring about 2 mm. It consists of two parts, a principal cavity, the **sinus venosus**, situated posteriorly, and an antero-superior, smaller portion, the **auricular appendix**.

The **sinus venosus** (*sinus venarum*) is the large quadrangular cavity, placed between the two venæ cavæ. Its walls, which are extremely thin, are connected in front and to the left with the right ventricle, and mesally with the left auricle, but are free in the rest of their extent.

The **right auricular appendix** (*auricula dextra*), so called from its fancied resemblance to a dog's ear, is a small conical muscular pouch, the margins of which present a

FIG. 417.—The right auricle and ventricle laid open, the anterior walls of both being removed.

dentated edge. It projects from the sinus forward and toward the left side, overlapping the root of the aorta.

The separation of the appendix from the sinus venosus is indicated externally by a groove, the **sulcus terminalis** (His), which extends from the front of the superior vena cava to the front of the inferior vena cava, and represents the line of union of the sinus venosus of the embryo with the primitive auricle. In the cavity of the auricle the separation is marked by a vertical, smooth, muscular ridge on the anterior wall, the **crista terminalis** (His) (Fig. 418). Behind the crista the internal surface of the auricle is smooth, while in front of it the muscle fibres of the wall are raised into parallel ridges resembling the teeth of a comb, and hence named the **musculi pectinati**.

To examine the interior of the right auricle, an incision should be made along its right border from the entrance of the superior vena cava to that of the inferior vena cava. A second cut is to be made from the centre of the first incision to the tip of the auricular appendix, and the flap raised.

¹ In the new nomenclature the auricle is called the atrium, and the auricular appendix is called the auricle.

The interior of the right auricle (Fig. 417) presents the following parts for examination:

Openings	{	Superior vena cava.	Valves	{	Eustachian.
		Inferior vena cava.			Coronary.
		Coronary sinus.			
		Foramina Thebesii.			
		Auriculoventricular.			
		Anterior cardiac veins.			
		Fossa ovalis.			
		Annulus ovalis.			
		Tuberculum Loweri.			
		Musculi pectinati.			
		Crista terminalis.			

The **superior vena cava** (*precava*) returns the blood from the upper half of the body, and opens into the upper and back part of the auricle, the direction of its orifice being downward and forward. Its opening has no valves.

The **inferior vena cava** (*postcava*), larger than the superior vena cava, returns the blood from the lower half of the body, and opens into the lowest part of the auricle near the septum, the direction of its orifice being upward and inward, and guarded by a rudimentary valve, the **Eustachian valve**. The blood which enters the auricle through the superior vena cava is directed downward and forward, *i. e.*, toward the auriculoventricular orifice, while that entering it through the inferior vena cava is directed upward and backward toward the auricular septum. This is the normal direction of the two currents in fetal life.

The **coronary sinus** (*sinus coronarius*) opens into the auricle, between the inferior vena cava and the auriculoventricular opening. It returns the blood from the substance of the heart, and is protected by an incomplete semicircular fold of the lining membrane of the auricle, the **coronary valve**, or **valve of Thebesius**.

The **foramina Thebesii** (*foramina venarum minimarum*) are depressions in the walls of the auricle; the majority of these are *culs-de-sac*, but about one third are the orifices of minute veins (*venae minimae cordis*), which return the blood directly from the muscle substance of the heart.

The **anterior cardiac veins** open into the lower fore part of the right auricle.

The **right auriculoventricular opening**, or the **tricuspid orifice** (*ostium venosum dextrum*), is the large oval aperture of communication between the right auricle and the ventricle; it will be described with the right ventricle.

The **Eustachian valve** (*valvula venae cavae inferioris* [*Eustachii*]) is situated in front of the orifice of the inferior vena cava. It is semilunar in form, its convex margin being attached to the anterior margin of the inferior caval orifice; its concave margin, which is free, terminates in two cornua, of which the left is continuous with the anterior edge of the annulus ovalis, while the right is lost on the wall of the auricle. The valve is formed by a duplicature of the lining membrane of the auricle, containing a few muscle fibres. *In the fetus* this valve is of large size, and tends to direct the blood from the inferior vena cava, through the foramen ovale, into the left auricle. *In the adult* it is occasionally large, and may assist in preventing the reflux of blood into the inferior vena cava; more commonly it is small, and its free margin presents a cribriform or filamentous appearance; occasionally it is altogether wanting.

The **coronary valve** or **valve of Thebesius** (*valvulae sinus coronarii* [*Thebesii*]) is a semicircular fold of the lining membrane of the auricle, protecting the orifice of the coronary sinus. It prevents the regurgitation of blood into the sinus during the contraction of the auricle. This valve is occasionally double.

The **fossa ovalis** is an oval depression corresponding to the situation of the **foramen ovale** in the fetus. It is situated at the lower part of the auricular septum, above and to the left of the orifice of the inferior vena cava. In fetal life an opening, the **foramen ovale**, exists at this point between the two auricles; almost immediately after birth the valve-like edge is pressed down by the increased pressure in the left auricle, and by the tenth day it passes to the annulus and closes the opening.

The **annulus ovalis** (*limbus fossae ovalis* [Vieussenii]) is the prominent oval margin of the fossa ovalis. It is most distinct *above* and at the sides; *below*, it is deficient. A small, slit-like, valvular opening is occasionally found, at the upper anterior margin of the fossa ovalis, which leads upward beneath the annulus into the left auricle; it is the remains of the fetal aperture between the two auricles.

FIG. 418. —Heart opened to show the interior of the right auricle and of the two ventricles, from in front. The wall of the right auricle is turned back to show the muscoli pectinati and the crista terminalis. The ventricular walls and the ventricular septum have been cut. The aortic valve is made more prominently visible in the drawing than it really is in nature.

The **tubercle of Lower** (*tuberculum intervenosum* [Loweri]) is a small projection on the interauricular septum between the fossa ovalis and the opening of the superior vena cava. It is most distinct in the hearts of quadrupeds; in man it is scarcely visible. It was supposed by Lower to direct the blood from the superior vena cava toward the auriculoventricular opening.

The *internal surface* of the right auricle is smooth, except in the appendix and adjacent part of the anterior wall of the sinus venosus, where the muscular wall is thrown into parallel ridges resembling the teeth of a comb, and hence named the

musculi pectinati. These end behind in a vertical smooth ridge, the **crista terminalis** (Fig. 418).

The **Right Ventricle** (*ventriculus dexter*) is pyramidal in form, and extends from the right auricle to near the apex of the heart. Its *antero-superior surface* is rounded and convex, and forms the larger part of the front of the heart. Its *under surface* is flattened, rests upon the Diaphragm, and forms a small part of the postero-inferior surface of the heart. Its *posterior wall* is formed by the septum between the two ventricles, the **interventricular septum** (*septum ventriculorum*), which bulges into the right ventricle, so that a transverse section of the cavity presents a semilunar outline. The basal and inner angle of the ventricle is prolonged into a conical pouch, the **infundibulum** (*conus arteriosus*), from which the pulmonary artery arises. The balance of the ventricle, the **body**, is the portion into which the auriculo-ventricular orifice opens. The **conus arteriosus** is marked off from the body of the ventricle by a muscular projection (*crista supraventricularis*). The walls of the right ventricle are thinner than those of the left, the proportion between them being as 1 to 3. The wall is thickest at the base, and gradually becomes thinner toward the apex.

To examine the interior of the right ventricle, its anterior wall should be turned downward and to the right in the form of a triangular flap. This is accomplished by making two incisions: (1) From the pulmonary artery to the apex of the ventricle parallel to, but a little to the right of, the anterior interventricular furrow; (2) another, starting from the upper extremity, of the first and carried outward parallel to, but a little below, the auriculoventricular furrow, care being taken not to injure the auriculoventricular valve.

The interior of the right ventricle presents for examination:

Openings	{ Auriculoventricular. Opening of the pulmonary artery.
Valves	{ Tricuspid. Semilunar.

Columnae carneae.

Chordae tendineae.

The **right auriculoventricular opening**, or the **tricuspid orifice** (*ostium venosum ventriculi dextri*), is the large oval aperture of communication between the auricle and ventricle. It is situated at the base of the ventricle, near the right border of the heart. The plane of this opening is nearly vertical. It is oval and about 3.75 cm. (1.5 inches) in diameter from side to side, surrounded by a fibrous ring and covered by the lining membrane of the heart; it is considerably larger than the corresponding aperture on the left side, being sufficient to admit the ends of four fingers. The circumference of the orifice is about 12 cm. (4.8 inches) in the male, and 10.5 cm. (4.2 inches) in the female. It is guarded by the tricuspid valve.

The **opening of the pulmonary artery** (*ostium arteriosum pulmonis*) is circular in form, and is situated at the summit of the conus arteriosus, close to the ventricular septum. It is placed above and to the left of the auriculoventricular opening, and is guarded by the pulmonary valve.

The **tricuspid valve** (*valvula tricuspidalis*) consists of three **segments** or **cusps** (*cuspides*) of a triangular or trapezoidal shape, each formed by a duplicature of the lining membrane of the heart, strengthened by intervening layers of fibrous tissue. The largest and most movable segment is placed toward the left side of the auriculoventricular opening, and is interposed between that opening and the infundibulum; hence it is called the **left** or **infundibular cusp** (*cuspis medialis*). Another segment is in relation with the right part of the front of the ventricle, the **right** or **marginal cusp** (*cuspis anterior*), and a third with its posterior wall, the **posterior** or **septal cusp** (*cuspis posterior*). The central part of each segment is

thick and strong; the lateral margins are thin and translucent. These segments are connected by their bases to the oval fibrous ring surrounding the auriculoventricular orifice (*annulus fibrosus dexter*), and by their sides with one another, so as to form a continuous annular membrane, which is attached around the margin of the auriculoventricular opening; their free margins and ventricular surfaces afford attachment to a number of delicate tendinous cords, the *chordae tendineae*. The *chordae tendineae* are connected with the adjacent margins of the principal segments of the valve, and are further attached to each segment in the following manner: (1) Three or four reach the attached margin of each segment, where they are continuous with the auriculoventricular tendinous ring. (2) Others, four to six in number, are attached to the central thickened part of each segment. (3) The most numerous and finest are connected with the marginal portion of each segment.

The *columnae carneae* (*trabeculae carneae*) are the rounded muscle columns which project from nearly the whole of the inner surface of the ventricle, excepting near the opening of the pulmonary artery, where the wall is smooth. They may be classified, according to their mode of connection with the ventricle, into three sets. The *first* set merely forms prominent *ridges* on the inner surfaces of the ventricle, being attached by their entire length on one side, as well as by their extremities. The *second* set are attached by their two extremities, but are free in the rest of their extent, forming *arches*; while a *third* set (*musculi papillares*) are continuous by their bases with the wall of the ventricle, while their apices give origin to the *chordae tendineae*, the *papillary muscles*. There are usually *two* papillary muscles, the *anterior* and the *posterior*; of these, the anterior is the larger; its *chordae tendineae* are connected with the right and left segments of the tricuspid valve. The posterior sometimes consists of two or three muscle columns; its *chordae tendineae* are connected with the posterior and the right segments of the tricuspid valve. In addition to these, some few *chordae* spring directly from the ventricular septum, or from small eminences on it, and pass to the left and posterior segments. A fleshy band, well marked in the sheep and some other animals, is frequently seen passing from the base of the anterior papillary muscle to the interventricular septum. From its attachments it may assist in preventing overdistention of the ventricle, and so has been named the *moderator band*.

The *pulmonary valve* (Fig. 418) consists of three semilunar segments (*valvulae semilunares a. pulmonalis*), two of which are *anterior* and one of which is *posterior*, formed by duplicatures of the lining membrane of the ventricle, strengthened by fibrous tissue. They are attached, by their outer convex margins, to the wall of the artery, at its junction with the ventricle, their inner borders being free, and directed upward in the lumen of the vessel. The free and attached margins of each are strengthened by a bundle of tendinous fibres, and the former presents, at its middle, a small projecting thickened nodule, consisting of bundles of interlacing connective-tissue fibres with branched connective-tissue cells and some few elastic fibres. Such a nodule is called the *corpus Arantii* (*noduli valvularum semilunarium [Arantii]*). From this nodule tendinous fibres radiate through the valve to its attached margin, but are absent from two narrow crescentic portions, the *lunulae* (*lunulae valvularum semilunarium*), placed one on either side of the nodule immediately adjoining the free margin.

The basal end of the pulmonary artery presents three dilatations opposite to the valve. These are the *pulmonary sinuses of Valsalva*. Similar sinuses exist between the semilunar valves and the commencement of the aorta; they are larger than the pulmonary sinuses.

In order to examine the interior of the left auricle, make an incision on the posterior surface of the auricle from the pulmonary veins on one side to those on the other, the incision being

carried a little way into the vessels. Make another incision from the middle of the horizontal one to the auricular appendix.

The **Left Auricle** (*atrium sinistrum*) is rather smaller than the right, but its walls are thicker, measuring about 3 mm.; it consists, like the right, of two parts, a **principal cavity** and an **auricular appendix**.

The **principal cavity** is cuboidal in form, and concealed in front by the pulmonary artery and aorta; in *front* and to the *right*, it is separated from the right auricle by the **auricular septum** (*septum atriorum*); *behind*, it receives on either side two pulmonary veins.

The **left auricular appendix** (*auricula sinistra*) is somewhat constricted at its junction with the principal cavity; it is longer, narrower, and more curved than that of the right side, and its margins are more deeply indented. It is directed forward and toward the right and overlaps the root of the pulmonary artery.

The interior of the left auricle presents the following parts for examination:

The openings of the four pulmonary veins.
Auriculoventricular opening.
Musculi pectinati.
Foramina Thebesii.

The **pulmonary veins**, four in number, open into the upper part of the posterior surface of the left auricle—two on either side of its middle line. They are not provided with valves. The two left veins frequently terminate by a common opening.

The **left auriculoventricular opening**, or **mitral orifice** (*ostium venosum ventriculi sinistri*), is the aperture of communication between the left auricle and the left ventricle. It is rather smaller than the corresponding opening on the right side.

The **musculi pectinati**, fewer and smaller than in the right auricle, are confined to the inner surface of the auricular appendix.

On the auricular septum may be seen a lunated impression bounded below by a crescentic ridge the concavity of which is turned upward. The depression is just above the fossa ovalis of the right auricle. The inner surface of the left auricle also shows **foramina Thebesii** and **venae minimae cordis**.

To examine the interior of the left ventricle, make an incision a little to the left of the anterior interventricular groove from the base to the apex of the heart, and carry it up from thence, a little to the left of the posterior interventricular groove, nearly as far as the auriculoventricular groove.

The **Left Ventricle** (*ventriculus sinister*) is longer and more conical in shape than the right ventricle, and on transverse section its cavity presents an oval or nearly circular outline. It forms a small part of the anterior surface of the heart and a considerable part of its postero-inferior surface. It also forms the apex of the heart by its projection beyond the right ventricle. Its walls are much thicker than those of the right side, the proportion being as 3 to 1.

Its interior (Fig. 419) presents the following parts for examination:

Openings {	Auriculoventricular.	Valves {	Mitral or Bicuspid.
	Aortic.		Semilunar.
	Chordae tendineae.		Columnae carnae.

The **left auriculoventricular opening** or the **mitral orifice** (*ostium venosum ventriculi sinistri*) is placed below and to the left of the aortic orifice. It is a little smaller than the corresponding aperture of the opposite side, admitting only two

fingers; but, like it, is broader in the transverse than in the antero-posterior diameter. Its right, posterior, and left sides are surrounded by a dense horseshoe-shaped, fibrous ring (*annulus fibrosus sinister*). The orifice is guarded by the mitral or bicuspid valve.

The **aortic opening** (*ostium arteriosum*) is a circular aperture, in front and to the right side of the auriculoventricular opening, from which it is separated by the aortic cusp of the mitral valve. Its orifice is guarded by the **aortic valve**, which consists of three semilunar segments. The portion of the ventricle immediately below the aortic orifice is often termed the **aortic vestibule**, and possesses fibrous instead of muscular walls.

FIG. 419.—The left auricle and ventricle laid open, the posterior walls of both being removed.

The **mitral** or **bicuspid valve** (*valvula bicuspidalis*) is attached to the circumference of the auriculoventricular orifice in the same way that the tricuspid valve is on the opposite side. It consists of two triangular cusps, formed by duplicatures of the lining membrane, strengthened by fibrous tissue, and containing a few muscle fibres. The cusps are of unequal size, and are larger, thicker, and stronger than those of the tricuspid valve. The larger segment, the **anterior** or **aortic cusp** (*cusps anterior*), is placed in front and to the right between the auriculoventricular and aortic orifices; the smaller, the **posterior** or **marginal cusp** (*cusps posterior*), is placed to the left and behind the opening. Two smaller cusps are usually found at the angles of junction of the larger. The cusps of the mitral valve are furnished with chordae tendineae, which are attached in a manner similar to those on the right side; they are, however, thicker, stronger, and less numerous.

The **aortic valve** consists of three semilunar segments (*valvulae semilunares aortae*), which surround the orifice of the aorta; two are posterior (right and left) and one anterior. They are similar in structure and in their mode of attachment to those of the pulmonary valve, but are larger, thicker, and stronger; the **lunulae** are more distinct and the **corpora Arantii** thicker and more prominent. Opposite

the segments the wall of the aorta presents slight dilatations, the **sinuses of Valsalva**, which are larger than those at the origin of the pulmonary artery.

The **columnae carneae** are of three kinds, like those upon the right side; but they are more numerous, and present a dense interlacement, especially at the apex, and upon the posterior wall. The **musculi papillares** are *two* in number, one being connected to the anterior, the other to the posterior wall; they are of large size, and terminate by free rounded extremities, from which the **chordae tendineae** arise. The chordae tendineae from each papillary muscle are connected to both cusps of the mitral valve.

The **interventricular septum** (*septum ventriculorum*) is directed obliquely backward and to the right, and is curved with the convexity toward the right ventricle; its margins correspond with the interventricular grooves. The greater portion of it is thick and fleshy (*septum musculare ventriculorum*), but its upper and posterior part, which separates the aortic vestibule from the lower part of the right auricle and upper part of the right ventricle is thin and fibrous, and is termed the **undefended or membranous part of the interventricular septum** (*septum membranaceum ventriculorum*). It is derived from the lower part of the aortic septum of the fetus, and an abnormal communication may exist at this part, owing to defective development of this septum.

FIG. 420.—Fibrous rings at the base of the ventricles. (Poirier and Charpy.)

Capacity of the Cavities of the Heart.—Each of the cavities of the heart is capable of holding about 100 c.c., but this is subject to considerable variation among different individuals.

Structure of the Heart.—The heart is a hollow muscular organ, and its walls are divisible into three coats—the **endocardium**, **myocardium**, and **epicardium**, or **visceral layer of the pericardium** (page 552).

The **endocardium** is a thin, smooth, serous membrane which lines and gives the glistening appearance to the internal surface of the heart; it assists in forming the valves by reduplications, and is continuous with the endothelial coat of the bloodvessels which pass to and emerge from the heart. It is composed of endothelial cells resting upon a fibroelastic membrane which contains unstriated muscle cells. The endocardium is more opaque on the left than on the right side of the heart, thicker in the auricles than in the ventricles, and thickest in the left auricle. It is thin on the *musculi pectinati* and on the *columnae carneae*, but thicker on the smooth parts of the auricular and ventricular walls and on the tips of the *musculi papillares*.

The **fibrous rings** (*annuli fibrosi*) surround the auriculoventricular and arterial orifices; they are stronger upon the left than on the right side of the heart, and are composed of dense white fibrous connective tissue. The auriculoventricular rings serve for the attachment of the muscle fibres of the auricles and ventricles, and also for the mitral and tricuspid valves; the

ring on the left side is closely connected by its right margin with the aortic arterial ring. Between these and the right auriculoventricular ring is a mass of fibrous tissue (*trigonum fibrosum*), and in some of the larger animals, as the ox and elephant, a nodule of bone, the *os cordis*.

The fibrous rings surrounding the arterial orifices serve for the attachment of the great vessels and semilunar valves. Each ring receives, at its ventricular margin, the attachment of the muscle fibres of the ventricles; its opposite margin presents three deep semicircular notches, within which the middle coat of the artery (which presents three convex semicircular segments) is firmly fixed, the attachment of the artery to its fibrous ring being strengthened by the thin cellular coat and serous membrane externally and by the endocardium within. It is opposite the margins of these semicircular notches, in the arterial rings, that the endocardium by its reduplication, strengthened by white fibrous tissue, forms the semilunar valves, the fibrous structure of the ring being continued into each of the segments of the valve. The middle coat of the artery in this situation is thin, and the sides of the vessels are dilated to form the sinuses of Valsalva.

The **myocardium** of the heart consists of bands and layers of muscle tissue which present an exceedingly intricate interlacement. It consists of (a) the fibres of the auricles, (b) the fibres of the ventricles, and (c) the auriculoventricular bundle of His.

FIG. 421.—The arrangement of the muscles of the auricles. (Poirier and Charpy.)

Fibres of the Auricles (Fig. 421).—These are disposed in two layers—a superficial layer common to both cavities, and a deep layer proper to each. The **superficial fibres** are more distinct on the anterior surface of the auricles, across the bases of which they run in a transverse direction, forming a thin but incomplete layer. Some of these fibres pass into the septum atriorum. The **internal or deep fibres** proper to each auricle consist of two sets, looped and annular fibres. The **looped fibres** pass upward over each auricle, being attached by two extremities to the corresponding auriculoventricular rings in front and behind. The **annular fibres** surround the auricular appendices, and form annular bands around the terminations of the veins and around the fossa ovalis.

The **fibres of the ventricles** are arranged in a complex manner, and various accounts have been given of their course and connections. The following description is based on the work of McCallum.¹ They consist of superficial and deep layers, all of which, with the exception of two, are inserted into the papillary muscles of the ventricles. The **superficial layers** consist of the following: (a) Fibres which spring from the tendon of the conus arteriosus and sweep downward and toward the left across the anterior interventricular furrow and around the apex of the heart, where they pass upward and inward to terminate in the papillary muscles of the left ventricle. Those which spring from the upper half of the tendon of the conus arteriosus pass to the anterior papillary muscle, those from the lower half to the posterior papillary muscle and the papillary muscles of the septum. (b) Fibres which arise from the right auriculoventricular ring and run diagonally across the back of the right ventricle and around its right border on to its anterior surface, where they dip beneath the fibres just described, and, crossing the interventricular groove, wind around the apex of the heart and terminate in the posterior papillary muscle of the left ventricle. (c) Fibres which spring from the left auriculoventricular ring, and, crossing the posterior interventricular furrow, pass successively into the right ventricle

¹ Johns Hopkins Hospital Reports, vol. ix.

and end in its papillary muscles. The *deep layers* are three in number; they arise in the papillary muscles of one ventricle and, curving in an S-shaped manner, turn in at the interventricular furrow and end in the papillary muscles of the other ventricle. The layer which is most superficial in the right ventricle lies next the lumen of the left, and *vice versa*. Those of the first layer almost encircle the right ventricle, and, crossing in the septum to the left, unite with the superficial fibres from the right auriculoventricular ring to form the posterior papillary muscle. Those of the second layer have a less extensive course in the wall of the right ventricle, and a correspondingly greater course in the left, where they join with the superficial fibres from the anterior half of the tendon of the conus arteriosus to form the papillary muscles of the septum. Those of the third layer pass almost entirely around the left ventricle and unite with the superficial fibres from the lower half of the tendon of the conus arteriosus to form the anterior papillary muscle. Besides the layers just described there are two bands which do not end in papillary muscles. One springs from the right auriculoventricular ring and crosses in the auriculoventricular septum; it then encircles the deep layers of the left ventricle and ends in the left auriculoventricular ring. The second band is apparently confined to the left ventricle; it is attached to the left auriculoventricular ring, and encircles the portion of the ventricles adjacent to the aortic orifice.

The **auriculoventricular bundle of His** (*fasciculus atrioventricularis* (Fig. 424) is the only direct muscle connection known to exist between the auricles and ventricles. It arises near the opening of the coronary sinus, where it is connected with the annular and septal fibres of the right auricle. These fibres converge, form a **node** (*node of Tawara*), and continue as a compact bundle which passes forward in the lower part of the *pars membranacea septi* to the upper limit of the muscle portion of the ventricular septum, and divides into right and left fasciculi. These run down to the right and left ventricles, one on either side of the interventricular septum, the left limb being just covered by endocardium, while the right limb, for a part of its course, is more deeply placed in the muscle layer. Each limb is enclosed in a layer of connective tissue, which isolates it from the musculature of the interventricular septum, but in the lower parts of the ventricles each fasciculus separates into numerous strands which enter the papillary muscles and spread over the entire internal surface of the ventricular muscle and form histological connections with the true cardiac muscle fibres. The right limb is the smaller of the two and

FIG. 422.—The muscular arrangement of the apex of the heart. (Poirier and Charpy.)

FIG. 423.—The arrangement of the muscle of the ventricle. (Poirier and Charpy.)

usually reaches the anterior papillary muscle by passing along the moderator band when this is present. The undivided portion of the auriculoventricular bundle consists of narrow, somewhat fusiform fibres, but its two divisions and their terminal strands are composed of Purkinje fibres. The bundle is not always easily recognized in the human heart, but is readily demonstrated in the heart of the sheep or calf.

A constant *bursa* or lubricating mechanism is in relation with the main bundle, according to Curran,¹ and a special artery, arising from the right coronary, enters the bundle at its beginning and follows it in direction.

The **Purkinje fibres** are very much larger in size than the cardiac cells, and differ from them in several ways. In longitudinal section they are quadrilateral in shape, being about twice as long as they are broad. The central portion of each fibre contains one or more nuclei and is made up of granular protoplasm, with no indication of striations, while the peripheral portion is clear and has distinct transverse striations. The fibres are intimately connected with each other, possess no definite sarcolemma, and do not branch.

FIG. 424.—Schematic representation of the auriculoventricular bundle of His. The bundle, represented in red, originates near the orifice of the coronary sinus, undergoes slight enlargement to form a node, passes forward to the ventricular septum, and divides into two limbs. The ultimate distribution cannot be completely shown in this diagram.

The **epicardium**, or **visceral layer of the pericardium**, is a serous membrane analogous in structure to the endocardium, but contains no smooth muscle tissue. It is thin, smooth, glistening, and transparent, and is reflected over the roots of the great vessels to the inner surface of the pericardial sac, forming there the **parietal layer of the pericardium**.

Applied Anatomy.—Clinical and experimental evidence go to prove that the auriculoventricular bundle conveys the impulse to systolic contraction from the auricular septum to the ventricles, and much attention has recently been paid to it, because it appears to become attacked by various disease processes and to lose much of its conducting power in many cases

¹ The Anatomical Record, December, 1909, vol. iii, No. 12.

of *Stokes-Adams disease* (heart block). This condition is characterized by a slow pulse, a tendency to syncopal or epileptiform seizures, and the fact that while the cardiac auricles beat at a normal rate, the ventricles contract much less frequently. The existence of a bursa in relation with the bundle suggests the possibility of a bursitis, in view of which these cardiac symptoms may be the result of acute rheumatism or other febrile diseases.

Vessels and Nerves.—The **arteries** supplying the heart are the right and left coronary from the aorta.

The **veins** terminate in the right auricle, and will be described with the general venous system.

The **lymphatics** end in the thoracic and right lymphatic ducts.

The **nerves** are derived from the **superficial** and **deep cardiac plexuses**, and from these plexuses obtain fibres of the vagus, spinal accessory, and sympathetic. The superficial cardiac plexus lies under the arch of the aorta. The deep cardiac plexus is in front of the tracheal bifurcation. The nerves from the plexuses are freely distributed both on the surface and in the substance of the heart, the separate filaments being furnished with small ganglia. A special system of ganglion cells and nerve fibres has been found¹ in the auriculoventricular bundle.

The Cardiac Cycle and the Action of the Valves.—By the contractions and pumping action of the heart the blood is forced through the arteries, capillaries, and veins of the systemic and pulmonic vascular systems. Normally, these contractions are rhythmic in character and occur at the rate of about seventy per minute. Each period of activity is followed by a period of rest, and during these two periods certain events take place in the various parts of the heart in regular sequential order. The period included between the occurrence of any one of these events and the recurrence of the same event constitutes a **cardiac cycle**, or **cardiac revolution**.

The cardiac cycle may be conveniently divided into three phases, which succeed one another, as follows: (1) A short, practically simultaneous contraction of both auricles, termed the *auricular systole*, followed, after a slight pause, by (2) a simultaneous, but more prolonged, contraction of both ventricles, named the *ventricular systole*, and (3) a period of rest during which the whole heart is relaxed, *i. e.*, in a state of *diastole*. The contraction process begins at the venous openings or in an area in the right auricle between the venae cavae, whence it spreads, in the form of a wave, over the auricles and then to and over the ventricles. The quick contraction of the auricles forces the blood contained in these chambers, through the auriculoventricular openings into the relaxed ventricles, which become fully distended. The contraction of the ventricles follows almost immediately. There ensues a rapid compression of their contained mass of blood and a relatively high pressure is thus developed which occasions the forcible closure of the auriculoventricular valves. These are prevented from being everted into the auricular cavities by their attachment to the papillary muscles through the intermediation of the chordae tendineae. The diminution in size of the ventricular cavities might be followed by a slackening of these tendinous cords were it not for the compensating effect of the active shortening of the papillary muscles which takes place shortly after the onset of the contraction of the general ventricular musculature. The pressure in the ventricles soon rises above that in the pulmonary artery and aorta. At that moment the valves at the orifices of these vessels are forced open and the blood is driven, by a sustained contraction, from the right ventricle into the pulmonary artery and from the left ventricle into the aorta. As soon as the ventricular systole ceases and the pressure in the pulmonary artery and aorta exceeds that in the ventricles the pulmonary and aortic valves close, thus preventing a regurgitation of the blood into the ventricles. While the ventricles are contracting blood is flowing from the veins into the auricles, where it accumulates and distends them. As the ventricles relax, the pressure of the blood in the auricles opens the auriculoventricular valves and blood now flows passively from the veins into the auricles and from these into the ventricles. The rapid accumulation of the blood in the ventricles leads to a floating up of the auriculoventricular

¹ J. Gordon Wilson, Proceedings of the Royal Society, B., 1909, vol. lxxxi.

valves which are shortly afterward pushed aside during the next succeeding auricular contraction.

It will be observed that each set of chambers contracts and relaxes alternately. However, the time occupied by the auricular contraction is short, while that occupied by the relaxation is long in comparison with the time occupied by the similar events in the ventricles. From the beginning of the ventricular diastole until the beginning of the next auricular systole the entire heart is at rest—the so-called *common pause* of the heart's chambers. The average duration of a cardiac cycle is about $\frac{8}{10}$ of a second, which may be divided, approximately, among its different phases as follows:

Auricular systole, $\frac{1}{10}$.
Ventricular systole, $\frac{3}{10}$.

Auricular diastole, $\frac{7}{10}$.
Ventricular diastole, $\frac{5}{10}$.

Common pause $\frac{4}{10}$.

As mentioned before, the contraction process, which begins at the mouths of the great veins, spreads with great rapidity over the auricles, and then to and over the ventricles. A slight delay is experienced by the contraction wave in passing from the auricles to the ventricles. This is due in all probability to the circumstance that the contraction wave must be conducted along a narrow bridge of muscle tissue which is more or less embryonic in character. This bridge of muscle tissue connecting the auricles with the ventricles, morphologically and physiologically, is the auriculoventricular bundle of His (page 567). In accordance with this view, the origin and conduction of the contraction process is a property of the muscle tissue, and the theory which embodies this view is known as the *myogenic theory* of the heart beat. Inasmuch as nerve cells and their axones are found in many parts of the heart, the auriculoventricular bundle included, it is thought by some that the origin and conduction of the stimulus giving rise to the contraction process is a property of the nerve tissue. The theory embodying this view is known as the *neurogenic theory* of the heart beat. It must be said, however, that many facts tend to demonstrate that the myogenic theory is the correct one. Whatever be the tissue in which the heart beat originates, the cause of the contraction must be sought in the heart itself; for the mammalian heart can be made to beat for a relatively long time when completely isolated from the body of the animal.

The cardiac muscle, therefore, does not depend for its contractions on the discharge of nerve impulses by the central nerve system, although the latter, through the extracardiac nerves, exercises a regulative influence on the heart's action, increasing or decreasing the rate or force of the heart beats in accordance with the physiological needs of the body. (G. Bachmann.)

Surface Form.—In order to show the extent of the heart in relation to the front of the thorax, draw a line from a point in the second left intercostal space, 4.5 cm. (nearly two inches) from the median line to the upper border of the third right costal cartilage, 3 cm. (one inch and a quarter) from the median line. This represents the base line or upper limit of the organ. Take a point in the fifth left intercostal space 8 cm. from the median line (about three and a quarter inches); this represents the apex of the heart. Draw a line from this apex point, with a slight convexity downward, to the junction of the seventh right costal cartilage to the sternum 2.5 cm. from the median line. This represents the lower limit of the heart. Join the right extremity of the first line—that is, the base line—with the right extremity of this line—that is, to the seventh right chondrosternal joint—with a slight curve outward, so that it projects about 3.5 cm. (one inch and a half) from the mid-line of the sternum. Lastly, join the left extremity of the base line and the apex point by a line curved slightly to the left.

The position of the various orifices is as follows—viz., the pulmonary orifice is situated in the upper angle formed by the articulation of the third left costal cartilage with the sternum; the aortic orifice is a little below and internal to this, behind the left border of the sternum, close to the articulation of the third left costal cartilage to this bone. The left auriculoventricular

opening is behind the sternum, rather to the left of the median line, and opposite the fourth costal cartilages. The right auriculoventricular opening is a little lower, opposite the fourth interspace and in the middle line of the body (Fig. 410).

A portion of the area of the heart thus mapped out is uncovered by lung, and therefore gives a dull note on percussion; the remainder, being overlapped by the lung, gives a more or less resonant note. The former is known as the *area of complete cardiac dulness*. The area of complete cardiac dulness is included between a line drawn from the centre of the sternum, on a level with the fourth costal cartilage, to the apex of the heart and a line drawn from the same point down the lower third of the mid-line of the sternum. Below, this area merges into the dulness which corresponds to the liver.

Applied Anatomy.—Wounds of the heart are often immediately fatal, but not necessarily so. They may be nonpenetrating, when death may occur from hemorrhage, if one of the coronary vessels has been wounded, or subsequently from pericarditis; or, on the other hand, the patient may recover. Even a penetrating wound is not necessarily fatal, if the wound is a small one. An attempt should be made to save the patient by means of a surgical operation. A trap-door flap comprising the whole thickness of the thoracic wall should be made. The hinges of the trap-door are the rib cartilages. The pericardium is exposed and freely opened, clots are removed, the wound in the heart is sought for, and when discovered is sutured. In a penetrating wound the sutures include the whole thickness of the heart, except the endocardium. Interrupted sutures should be used, and each one had better be tied during diastole. A number of successful operations of this character have been performed.

Peculiarities in the Vascular System of the Fetus (Fig. 426).

The chief peculiarities in the heart of the fetus are the direct communication between the two auricles through the foramen ovale, and the large size of the Eustachian valve. There are also several minor peculiarities. Thus, the position of the heart is vertical until the fourth month, when it commences to assume an oblique direction. Its size is also very considerable as compared with the body, the proportion at the second month being 1 to 50; at birth it is as 1 to 120; while in the adult the average is about 1 to 160. At an early period of fetal life the auricular portion of the heart is larger than the ventricular, the right auricle being more capacious than the left; but toward birth the ventricular portion becomes the larger. The thickness of both ventricles is at first about equal, but toward birth the left becomes much the thicker of the two.

The **foramen ovale** (Fig. 425) is situated at the lower and back part of the auricular septum, forming a communication between the auricles. It remains as a free oval opening until the middle period of fetal life. About this period a fold grows up from the posterior wall of the auricle to the left of the foramen ovale, and advances over the opening so as to form a sort of valve, which allows the blood to pass only from the right to the left auricle, but not in the opposite direction.

The **Eustachian valve** (Fig. 425) projects upward in front of the opening of the inferior vena cava, and tends to direct the blood from this vessel through the foramen ovale into the left auricle.

The peculiarities in the arterial system of the fetus are the communication between the pulmonary artery and the descending aorta by means of the **ductus arteriosus**, and the continuation of the internal iliac arteries as the **umbilical arteries** to the placenta.

The **ductus arteriosus** (Fig. 426) is a short tube, about 10 mm. (half an inch) in length at birth, and 2 mm. (one-twelfth of an inch) in diameter. In the early condition it forms the continuation of the pulmonary artery, and opens into the descending aorta just below the origin of the left subclavian artery, and so conducts the greater part of the blood from the right ventricle into this vessel. When the branches of the pulmonary artery have become larger relatively to the ductus arteriosus, the latter is chiefly connected to the left pulmonary artery; and the fibrous cord (*ligamentum arteriosum*), which is all that remains of the ductus arteriosus in later life, will be found to be attached to the root of that vessel. Occasionally a small lumen persists in the ligamentum arteriosum.

The umbilical or hypogastric arteries are continued from the internal iliacs, along the sides of the bladder to its apex; they pass out of the abdomen at the umbilicus and are carried in the umbilical cord to the placenta. They convey the blood which has circulated in the system of the fetus to the placenta.

The peculiarities in the venous system of the fetus are the communications established between the placenta and the liver and portal vein, through the umbilical vein; and between the umbilical vein and the inferior vena cava through the ductus venosus.

FIG. 425.—The right auricle of a fetal heart (eighth month). Enlarged. (Spalteholz.)

Fetal Circulation (Fig. 426).—The blood destined for the nutrition of the fetus is returned from the placenta to the fetus by the umbilical vein. This vein enters the abdomen at the umbilicus, and passes upward along the free margin of the suspensory ligament of the liver to the under surface of that organ, where it gives off two or three branches to the left lobe, one of which is of large size, and others to the quadrate and Spigelian lobes. At the transverse fissure it divides into two branches; of these, the larger is joined by the portal vein and enters the right lobe; the smaller branch continues outward, under the name of the ductus venosus, and joins the left hepatic vein at the point of junction of that vessel with the inferior vena cava. The blood, therefore, which traverses the umbilical vein reaches the inferior vena cava in three different ways; the greater quantity circulates through the liver with the portal venous blood before entering the inferior vena cava by the hepatic veins; some enters the liver directly, and is also returned to the inferior vena cava by the hepatic veins; the smaller quantity passes directly into the inferior vena cava by the junction of the ductus venosus with the left hepatic vein.

In the inferior vena cava (postcava) the blood carried by the ductus venosus and hepatic veins becomes mixed with that returning from the lower extremities and wall of the abdomen. It enters the right auricle, and, guided by the Eustachian valve, passes through the foramen ovale into the left auricle, where it becomes mixed with a small quantity of blood returned from the lungs by the pulmonary veins. From the left auricle it passes into the left ventricle, and from the left ventricle into the aorta, by means of which it is distributed almost entirely to the head and upper extremities, a small quantity being probably carried into the

descending aorta. From the head and upper extremities the blood is returned by the tributaries of the superior vena cava (precava) to the right auricle, where it becomes mixed with a small portion of the blood from the inferior vena cava. From the right auricle it descends over the Eustachian valve into the right ventricle,

FIG. 426.—Plan of the fetal circulation. In this plan the figured arrows represent the kind of blood, as well as the direction which it takes in the vessels. Thus, arterial blood is figured >>—.....>; venous blood, >>—.....>; mixed (arterial and venous) blood, >>.....>.

and from the right ventricle passes into the pulmonary artery. The lungs of the fetus being inactive, only a small quantity of the blood of the pulmonary artery is distributed to them by the right and left pulmonary arteries, and is returned by the pulmonary veins to the left auricle; the greater part passes through the ductus

arteriosus into the commencement of the descending aorta, where it becomes mixed with the blood transmitted by the left ventricle into the aorta. Through this vessel it descends to supply the lower extremities and viscera of the abdomen and pelvis, the chief portion being, however, conveyed by the umbilical arteries to the placenta.

From the preceding account of the circulation of the blood in the fetus it will be seen—

1. That the placenta serves the purposes of nutrition, respiration, and excretion, receiving the impure blood from the fetus, and returning it charged with additional nutritive material.

2. That nearly the whole of the blood of the umbilical vein traverses the liver before entering the inferior vena cava; hence the large size of this organ, especially at an early period of fetal life.

3. That the right auricle is the point of meeting of a double current, the blood in the inferior vena cava being guided by the Eustachian valve into the left auricle, while that in the superior vena cava descends into the right ventricle. At an early period of the fetal life it is somewhat probable that the two streams are distinct, for the inferior vena cava opens almost directly into the left auricle, and the Eustachian valve would tend to exclude the current along the vein from entering the right ventricle. At a later period, as the separation between the two auricles becomes more distinct, it seems more probable that mixture of the two streams must take place.

4. The pure blood carried from the placenta to the fetus by the umbilical vein, mixed with the blood from the portal vein and the inferior vena cava, passes almost directly to the arch of the aorta, and is distributed by the branches of that vessel to the head and upper extremities; hence the large size and advanced development of those parts at birth.

5. The blood contained in the descending aorta, largely derived from that which has already circulated through the head and upper limbs, together with a small quantity from the left ventricle, is distributed to the lower extremities; hence the small size and less advanced development of these parts at birth.

Changes in the Vascular System at Birth.—At birth, when respiration is established, an increased amount of blood from the pulmonary artery passes through the lungs, which now perform their office as respiratory organs, and at the same time the placental circulation is cut off. Soon after birth the foramen ovale is closed by the valvular edge being pressed against the annulus ovalis, the pressure being due to respiration, which increases the pressure in the left auricle. The structures fuse, and closure is usually complete by about the tenth day after birth. The valvular fold above mentioned becomes adherent to the margins of the foramen for the greater part of its circumference, but above a slit-like opening is left between the two auricles which sometimes remains persistent.

The *ductus arteriosus* begins to contract immediately after respiration is established, usually becomes completely closed from the fourth to the tenth day, and ultimately degenerates into an impervious cord which serves to connect the left pulmonary artery to the arch of the aorta.

Of the *umbilical* or *hypogastric arteries*, the portion continued on to the bladder from the trunk of the corresponding internal iliac remains pervious as the superior vesical artery, and the part extending from the side of the bladder to the umbilicus becomes impervious between the second and fifth days after birth, and projects as a fibrous cord toward the abdominal cavity, carrying on it a fold of peritoneum.

The *umbilical vein* and the *ductus venosus* become impervious between the second and fifth days after birth, and ultimately dwindle to fibrous cords, the former becoming the round ligament of the liver, the latter the ligamentum venosum of the liver.

THE ARTERIES.

THE arteries are cylindrical tubular vessels which serve to convey blood from both ventricles of the heart to every part of the body. These vessels were named arteries (*ἀρτήρ*, air; *τηρεῖν*, to contain) from the belief entertained by the ancients that they contained air. Galen is believed to have been the first to show that during life they contain blood.

The *distribution* of the systemic arteries is like a highly ramified tree, the common trunk of which, formed by the aorta, commences at the left ventricle of the heart, the smallest ramifications corresponding to the periphery of the body and the contained organs. The arteries are found in nearly every part of the body, with the exception of the hairs, nails, epidermis, cartilages, and cornea; and the larger trunks usually occupy the most protected situations, running, in a limb, along the flexor side, where they are less exposed to injury.

There is considerable variation in the *mode of division* of the arteries; occasionally a short trunk subdivides into several branches at the same point, as we observe in the celiac and thyroid axes; or the vessel may give off several branches in succession, and still continue as the main trunk, as is seen in the arteries of the limbs; but the usual division is dichotomous; as, for instance, the aorta dividing into the two common iliacs, and the common carotid into the external and internal carotids.

A branch of an artery is smaller than the trunk from which it arises; but if an artery divides into two branches, the combined cross-section area of the two vessels is, in nearly every instance, somewhat greater than that of the trunk; and the combined cross-section area of all the arterial branches greatly exceeds that of the aorta; so that the arteries collectively may be regarded as a cone, the apex of which corresponds to the aorta, the base to the capillary system.

The arteries, in their distribution, communicate with one another, forming what are called **anastomoses** or **inosculations** (Fig. 427); and these communications are very free between the large as well as between the smaller branches. An anastomosis between trunks of equal size is found where great activity of the circulation is requisite, as at the base of the brain; here the two vertebral arteries unite to form the basilar, and the two internal carotid arteries are connected by a short communicating trunk; it is also found in the abdomen, the intestinal arteries having very ample anastomoses between their larger branches. In the limbs the anastomoses are most numerous and of largest size around the joints, the branches of an

FIG. 427.—Diagram showing the anastomosis of arteries. (Poirier and Charpy.)

artery above anastomosing with branches from the vessels below; these anastomoses are of considerable interest to the surgeon, as it is by their enlargement that a **collateral circulation** is established after the application of a ligature to an artery. The smaller branches of arteries anastomose more frequently than the larger, and between the smallest twigs these inosculations become so numerous as to constitute a close network that pervades nearly every tissue of the body. A **terminal artery** is one which forms no anastomoses. Such vessels are believed to exist in the brain, spleen, kidneys, lungs, mesentery, and papillary layer of the skin.

Throughout the body generally the larger arterial branches usually pursue a straight course, but in certain situations they are tortuous; thus, the facial arteries in their course over the face, and the arteries of the lips, are extremely tortuous in their course, to accommodate themselves to the movements of the parts. The uterine arteries are also tortuous, to accommodate themselves to the increase of size which the organ undergoes during pregnancy.

The arteries are dense in structure, of considerable strength, highly elastic, and, when divided, they usually preserve, although empty, their cylindrical form.

Histology of Arteries and Capillaries.—An artery consists of an endothelial tube covered by certain accessory coats.

The coats of an artery are: (1) **internal coat**, or *tunica intima*; (2) a **middle coat**, or *tunica media*; and (3) an **external coat**, or *tunica adventitia* (Fig. 413).

1. The **inner coat** (*tunica intima*) consists of endothelial cells resting upon some **subendothelial fibroelastic tissue**. Limiting the intima is a wavy band of yellow elastic tissue called the **internal elastic lamina**. In small arteries the endothelial cells rest upon the elastic lamina. In large arteries (aorta, pulmonary a.) the elastic tissue forms the **fenestrated membrane of Henle**.

2. The **middle coat** (*tunica media*) consists of muscle, elastic tissue, and white fibrous tissue. In medium-sized arteries the smooth muscle tissue is circularly arranged, with only a small quantity of elastic tissue here and there. In small arteries the elastic tissue is absent; in the

large arteries the elastic tissue predominates; in some vessels (retinal, first part of aorta, and pulmonary artery) the elastic tissue may entirely replace the muscle tissue. Occasionally longitudinally arranged muscle tissue is seen in the media. In medium-sized arteries the media is bounded by a layer of elastic tissue called the **external elastic lamina**.

3. The **external coat** (*tunica adventitia*) is called the fibrous coat. It contains fibroelastic tissues, and in some arteries fibres of nonstriated muscle longitudinally arranged. It contains the nutrient vessels, nerves, and lymphatics of the arteries. As the arteries diminish in size the coats likewise become thinner. The endothelial cells rest upon the internal elastic lamina; the media becomes

FIG. 428.—Transverse section of part of the wall of the posterior tibial artery. $\times 75$. A. Endothelial and sub-endothelial layers of inner coat. B. Elastic layer (fenestrated membrane) of inner coat, appearing as a bright line in section. C. Muscle layer (middle coat). D. Outer coat, consisting of connective-tissue bundles. In the interstices of the bundles are some connective-tissue nuclei, and, especially near the muscular coat, a number of elastic fibres cut across. (Schäfer.)

reduced to a few layers of muscle fibres, and the adventitia is represented by some bundles of fibroelastic tissue. This represents the **precapillary arteriole**, and it gradually becomes the capillary.

Capillaries are small endothelial tubes connecting arterial and venous systems. They vary from $\frac{1}{5000}$ to $\frac{1}{2000}$ of an inch (5μ to 13μ) in diameter, and about $\frac{1}{20}$ of an inch (500μ) in length. The endothelial cells are thin, flat, and irregular in outline; the darkly staining nucleus usually causes a bulging of the cell, as it is thicker than the protoplasmic portion of the cells. These cells are held together by a small amount of cement substance, and are considered by many to have the property of *phagocytosis*. Small openings called *stomata* are frequently noted between these cells, but they are considered artefacts. Capillaries anastomose and form vast networks. **Ampullae**, **sinusoids**, **retia mirabilia**, **sinuses**, and **anastomoses** are forms of capillaries seen in certain organs and tissues.

Bloodvessels of the Bloodvessel Wall.—Many small bloodvessels, the **vasa vasorum**, enter the adventitia; from these vessels branches are sent into the media, but not the intima.

The latter is nourished by the blood that flows over it. They may arise from the vessels to which they are distributed or take origin from an adjacent vessel. The blood is returned from the walls of the vessels by small veins.

Lymphatics.—Distinct lymphatic vessels may exist in the adventitia, but are represented by *lymph spaces* in the other coats. Lymph capillaries often surround small bloodvessels, or a small bloodvessel may lie in a *perivascular lymph space*.

Nerves.—Arteries are supplied with nerves, myelinic and amyelinic. A network of nerve fibres may surround a vessel, and usually capillaries are so surrounded. In the arteries a network of nerves exists in the media. These nerves supply the muscle fibres, and are called *vasomotor nerves*. According to Stöhr, nerve endings are found in the endothelium of the capillaries, giving them the power of contractility.

The **Arterial Sheath** (*vagina vasis*) surrounds the artery. It is composed of connective tissue, and is attached to the vessel at numerous points by fibrous tissue.

THE PULMONARY ARTERY (A. PULMONALIS) (Figs. 432, 436).

The **pulmonary artery** conveys the venous blood from the heart to the lungs. It is a short, wide vessel, about two inches (5 cm.) in length and one and one-fifth inches (30 mm.) in diameter, *arising* from the left side of the base (*conus arteriosus*) of the right ventricle, in front of the aorta. It extends obliquely upward and backward, passing at first in front of and then to the left of the ascending aorta, as far as the under surface of the arch, where it divides, about on a level with the intervertebral substance between the fifth and sixth thoracic vertebræ, into right and left branches of nearly equal size.

Relations.—The whole of the vessel is contained, together with the ascending aorta, in the pericardium. It is enclosed with the aorta in a single tube of the serous pericardium, which is continued upward upon them from the base of the heart and connects them together. The fibrous layer of the pericardium becomes gradually lost upon the external coats of its two branches. In *front*, the pulmonary artery is separated from the anterior extremity of the second left intercostal space by the pleura and left lung, in addition to the pericardium; it rests at first upon

the ascending aorta, and higher up lies in front of the left auricle on a plane posterior to the ascending aorta. On *either side* of its origin is the appendix of the corresponding auricle and a coronary artery, the left coronary artery passing, in the first part of its course, behind the vessel. The superficial cardiac plexus lies above its bifurcation, between it and the arch of the aorta.

The **right branch of the pulmonary artery** (*ramus dexter a. pulmonalis*), longer and larger than the left, runs horizontally outward to the root of the right lung, where it divides into two branches, of which the lower and larger supplies the middle and lower lobes; the upper and smaller is distributed to the upper lobe. It has *in front* of it the ascending aorta, the superior vena cava, and the right phrenic nerve. It has *behind* it the right bronchus. *Above* it is the arch of the aorta. *Below* it is the right auricle.

The **left branch of the pulmonary artery** (*ramus sinister a. pulmonalis*), shorter and somewhat smaller than the right, passes horizontally to the root of the left lung, where it divides into two branches for the two lobes. *In front* of it and below it are the pulmonary veins of the left side. *Behind* are the descending aorta and the left bronchus. *Above* it are the arch of the aorta, the left recurrent laryngeal nerve, and the ductus arteriosus. The left bronchus in a portion of its course lies below as well as behind.

The root of the left pulmonary artery is connected to the under surface of the arch of the aorta by a short fibrous cord, the **ligamentum arteriosum**; this is the remains of a vessel peculiar to fetal life, the **ductus arteriosus**.

The terminal branches of the pulmonary artery will be described with the anatomy of the lung.

Applied Anatomy.—Stenosis of the pulmonary artery, either with, or, more rarely, without defective formation of the interventricular septum, is one of the commonest congenital defects of the heart. It may be due either to fetal endocarditis or to maldevelopment of the bulbus cordis. As in most forms of congenital heart disease, the child is cyanosed (*morbis coeruleus*), especially when excited or on exertion, and rarely lives to grow up, commonly dying of heart failure in infancy, or of pulmonary tuberculosis or intercurrent disease in childhood. The chief signs of the condition are the loud, harsh systolic cardiac murmur best heard over the second left costal cartilage, cyanosis, clubbing of the finger tips, and the presence of an excess of red corpuscles in the blood.

Embolism of the pulmonary artery by a clot of blood coming from the right side of the heart in patients with heart disease, or from a thrombosed vein in cases, for example, of influenza, enteric fever, puerperal sepsis, or fractured limbs, is a common cause of sudden or rapid death. The patient may cry out with sudden excruciating pain in the precordia when the detached embolus lodges, and after a brief period of intense dyspnea, pallor, and anguish, die.

A few cases of surgical interference in embolism of the pulmonary artery are on record. Several were in a measure successful, death being usually due to septic complications, such as pleurisy and pericarditis. (Cf. Kreuzer, Centralblatt für Chirurgie, No. 21, 1909.)

THE AORTA (Figs. 431, 432).

The **aorta**, or **arteria magna**, is the main trunk of a series of vessels which convey the oxygenated blood to the tissues of the body for their nutrition. It commences at the upper part of the left ventricle, where it is about one and one-eighth inches (28 mm.) in diameter; and, after ascending for a short distance, arches backward and to the left side, over the root of the left lung, then descends within the thorax on the left side of the vertebral column, passes through the aortic opening in the Diaphragm, and, entering the abdominal cavity, terminates, considerably diminished in size, about seven-tenths of an inch (17.5 mm.) in diameter, opposite the lower border of the fourth lumbar vertebra, where it divides into the right and left common iliac arteries. Hence, it is divided into the **ascending aorta**, the **arch of the aorta**, and the **descending aorta**, which last is again divided into the **thoracic aorta** and the **abdominal aorta**, from the position of these parts.

THE ASCENDING AORTA (AORTA ASCENDENS).

The **ascending aorta** is about two inches (5 to 6 cm.) in length. It commences at the base of the left ventricle, on a level with the lower border of the third costal cartilage, behind the left half of the sternum; it passes obliquely upward, forward, and to the right, as high as the upper border of the second right costal cartilage,

FIG. 431.—The thoracic aorta and its relations. (Poirier and Charpy.)

describing a slight curve in its course, and being situated, when distended, about a quarter of an inch behind the posterior surface of the sternum. At its origin it presents, opposite the segments of the aortic valve, three small dilatations called the **sinuses of Valsalva**. At the union of the ascending with the transverse part of the aorta the caliber of the vessel is increased, owing to a bulging outward of its right wall. This dilatation is termed the **great sinus of the aorta** (*bulbus aortae*). A section of the aorta opposite this part is somewhat oval in outline. The ascending aorta is contained within the pericardium, and, together with the pulmonary artery, is invested in a tube of serous membrane, continued on to them from the surface of the heart.

Relations.—The ascending aorta is largely covered (ventrad) at its commencement by the trunk of the pulmonary artery and the right auricular appendix, and, higher up, is separated from the sternum by the pericardium, the right pleura, and anterior margin of the right lung,

some loose areolar tissue, and the remains of the thymus gland; *behind*, it rests upon the right pulmonary artery, left auricle, and the right bronchus. On the *right side* it is in relation with the superior vena cava and right auricle; on the *left side*, with the pulmonary artery.

Branches.—The only branches of the ascending aorta are the **coronary arteries** which supply the heart. They are two in number, right and left, arising near the commencement of the aorta immediately above the attached margin of the semi-lunar valves.

The Coronary Arteries (Fig. 432).—The **right coronary artery** (*a. coronaria [cordis] dextra*), about the size of a crow's quill, *arises* from the anterior sinus of Valsalva. It passes forward between the pulmonary artery and the right auricular appendix, then runs obliquely to the right side, in the groove between the right auricle and ventricle, and, curving around the right border of the heart, runs to the left along its postero-inferior surface as far as the postero-inferior interventricular groove, where it divides into two branches, one of which, the **transverse**, continues onward in the groove between the left auricle and ventricle, and anastomoses with the left coronary; the other, the **descending** (*ramus descendens posterior a. coronariae [cordis] dextrae*), courses along the postero-inferior interventricular furrow, supplying branches to both ventricles and to the septum, and anastomosing at the apex of the heart with the descending branches of the left coronary.

This vessel sends a large branch, the **marginal**, along the thin margin of the right ventricle, to the apex, which in its course gives off numerous small branches to the anterior and posterior surfaces of the right ventricle. It also gives off a branch, the **infundibular**, which ramifies over the front part of the conus arteriosus of the right ventricle. A small branch of the right coronary is said to supply the auriculoventricular bundle of His (see p. 568).

The **left coronary artery** (*a. coronaria [cordis] sinistra*), larger than the former, *arises* from the left posterior sinus of Valsalva; it passes forward between the pulmonary artery and the left auricular appendix, and divides into two branches. Of these, one, the **transverse**, passes transversely outward in the left auriculo-ventricular groove, and winds around the left border of the heart to its postero-inferior surface, where it anastomoses with the transverse branch of the right coronary; the other, the **descending** (*ramus descendens anterior a. coronariae [cordis] sinistrae*), passes along the antero-superior interventricular groove to the apex of the heart, where it anastomoses with the descending branches of the right coronary. The left coronary supplies the left auricle and its appendix, gives branches to both ventricles, and numerous twigs to the pulmonary artery and commencement of the aorta.

Peculiarities.—These vessels occasionally arise by a common trunk, or their number may be increased to three, the additional branch being of small size. More rarely there are two additional branches.

Applied Anatomy.—The sudden blocking of a coronary artery by an embolus, or its more gradual obstruction by arterial disease or thrombosis, are common causes of sudden death in persons past middle age. If the obstruction to the passage of blood is incomplete, true Angina pectoris may occur. In this condition the patient is suddenly seized with a spasm of agonizing pain in the precordial region and down the left arm, together with an indescribable sense of anguish. He may die in such an attack, or succumb a few hours or days later from heart failure, or he may survive a number of attacks.

FIG. 434.—Horizontal section through the sixth thoracic vertebra—upper surface of the lower segment—showing the ascending portion of the aortic arch, the thoracic aorta, and related structures.

THE ARCH OF THE AORTA (AROUS AORTAE).

The arch, or transverse aorta, commences at the level of the upper border of the second chondrosternal articulation of the right side, and passes at first upward, backward, and to the left in front of the trachea; it is then directed backward on the left side of the trachea, and finally passes downward on the left side of the body of the fourth thoracic vertebra, at the lower border of which it becomes continuous with

the descending aorta. It thus forms two curvatures, one with its convexity upward, the other with its convexity forward and to the left. Its upper border is usually about an inch below the upper margin of the sternum.

FIG. 435.—Horizontal section through the fourth thoracic vertebra—upper surface of the lower segment. The cut is made at the lower part of the transverse portion of the aortic arch.

Relations.—The arch of the aorta is covered *in front* by the pleuræ and anterior margins of the lungs, and by the remains of the thymus gland. As the vessel runs backward its *left* side is in contact with the left lung and pleura. Passing downward on the left side of this part of the arch are four nerves; in order from before backward these are the left

phrenic, the inferior cervical cardiac branch of the left vagus, the superior cardiac branch of the left sympathetic, and the trunk of the left vagus. As the last nerve crosses the arch it gives off its recurrent laryngeal branch, which hooks around below the vessel and then passes upward on its right side. The left superior intercostal vein runs obliquely upward and forward, on the left side of the arch between the phrenic and vagus nerves. On the *right* are the deep cardiac plexus, the left recurrent laryngeal nerve, the œsophagus, and thoracic duct; the trachea lies behind and to the right of the vessel. *Above* are the innominate, left common carotid, and left subclavian arteries, which arise from the convexity of the arch and are crossed close to their origins by the left innominate vein. *Below* are the bifurcation of the pulmonary artery, the left bronchus, the ligamentum arteriosum, the superficial cardiac plexus, and the left recurrent laryngeal nerve. As already stated, the ligamentum arteriosum connects the commencement of the left pulmonary artery to the aortic arch.

Between the origin of the left subclavian artery and the attachment of the ductus arteriosus the lumen of the fetal aorta is considerably narrowed, forming what is termed the **aortic isthmus** (*isthmus aortae*), while immediately beyond the ductus arteriosus the vessel presents a fusiform dilatation which His has named the **aortic spindle** (*aortenspindel*)—the point of junction of the two parts being marked in the concavity of the arch by an indentation or angle. These conditions persist, to some extent, in the adult, where His found that the average diameter of the spindle exceeded that of the isthmus by 3 mm. (about one-eighth of an inch).

Peculiarities.—The height to which the aorta rises in the thorax is usually about an inch below the upper border of the sternum; but it may ascend nearly to the top of that bone. Occasionally it is found an inch and a half, more rarely two or even three inches, below this point.

In Direction.—Sometimes in man, as is normal in birds, the aorta arches over the root of the right instead of the left lung, and passes down on the right side of the vertebral column; such an arrangement is usually found to be associated with transposition of other viscera. Less frequently, the aorta, after arching over the root of the right lung, is directed to its usual position on the left side of the vertebral column, this peculiarity not being accompanied by any transposition of the viscera.

In Conformation.—The aorta occasionally divides, as in some quadrupeds, into an ascending and descending trunk, the former of which is directed vertically upward, and subdivides into three branches, to supply the head and upper extremities. Sometimes the aorta subdivides soon after its origin into two branches, which soon reunite. In one of these cases the oesophagus and trachea were found to pass through the interval left by the division of the aorta; this is the normal condition of the vessel in the reptilia.

Applied Anatomy.—Of all the vessels of the arterial system, the aorta, and more especially its arch, is most frequently the seat of disease; hence it is important to consider some of the consequences that may ensue from *aneurism* of this part. Aortic aneurisms usually occur along a spiral line, the so-called "surf-line of the aorta," which begins at the anterior sinus of Valsalva and is lost in the dorsomesal wall of the descending aorta, as shown in Fig. 436.

It will be remembered that the ascending aorta is contained in the pericardium, just behind the sternum, being crossed at its commencement by the pulmonary artery and right auricular appendix, and having the right pulmonary artery behind, the superior vena cava on the right side, and the pulmonary artery and left auricle on the left side.

Aneurism of the ascending aorta, in the situation of the sinuses of Valsalva, in the great majority of cases, affects the anterior sinus; this is mainly owing to the fact that the regurgitation of blood upon the sinuses seems to take place chiefly on the anterior aspect of the vessel. As the aneurismal sac enlarges it may compress any or all of the structures in immediate proximity to it, but chiefly project toward the right anterior side, and, consequently, interferes mainly with those structures which have a corresponding relation with the vessel. In the majority of cases it bursts into the cavity of the pericardium, the patient suddenly drops dead, and, upon a postmortem examination, the pericardial sac is found full of blood; or it may compress the right auricle, or the pulmonary artery and adjoining part of the right ventricle, and open into one or the other of these parts, or may press upon or even rupture into the superior vena cava.

Aneurism of the ascending aorta, originating above the sinuses, most frequently implicates the right anterior wall of the vessel, where, as has been explained, there exists a normal dilatation, the great sinus of the aorta; this is probably mainly owing to the blood being impelled against this part. The direction of the aneurism is also chiefly toward the right of the median line. It attains a large size and projects forward, it may cause absorption of the sternum and the cartilages of the ribs, usually on the right side, and appears as a pulsating tumor on the front of the thorax, just below the manubrium; or it may burst into the pericardium, or may compress or open into the right lung, the trachea, bronchi, or oesophagus.

Regarding the *arch of the aorta*, the student is reminded that the vessel lies on the trachea, the oesophagus, and thoracic duct; that the left recurrent laryngeal nerve winds around it; and that from its upper part are given off three large trunks, which supply the head, neck, and upper

FIG. 436.—The "surf-line of the aorta," showing the commoner points of origin of aneurisms.

extremities. An aneurismal tumor, taking origin from the posterior part of the vessel, may press upon the trachea, impede the breathing, or produce cough, hemoptysis, or stridulous breathing, or it may ultimately burst into that tube, producing fatal hemorrhage. Again, its pressure on the laryngeal nerves may give rise to symptoms which so accurately resemble those of laryngitis that the operation of tracheotomy has in some cases been resorted to, from the supposition that disease existed in the larynx; or it may press upon the thoracic duct and destroy life by inanition; or it may involve the œsophagus, producing dysphagia; or may burst into the œsophagus, when fatal hemorrhage will occur. Again, the innominate artery, or the subclavian, or left carotid, may be so obstructed by clots as to produce a weakness, or even a disappearance, of the pulse in one or the other wrist or in the left temporal artery; or the tumor may present itself at or above the manubrium, generally either in the median line or to the right of the sternum, and may simulate an aneurism of one of the arteries of the neck.

Branches (Figs. 432 and 433).—The branches given off from the arch of the aorta are three in number—the **innominate**, the **left common carotid**, and the **left subclavian arteries**.

FIG. 437.—Relation of great vessels at base of a fetal heart, seen from above (enlarged). (From a preparation in the Museum of the Royal College of Surgeons of England.)

Peculiarities. Position of the Branches.—The branches, instead of arising from the highest part of the arch (their usual position), may be moved more to the right, arising from the commencement of the transverse or upper part of the ascending portion; or the distance from one another at their origin may be increased or diminished, the most frequent change in this respect being the approximation of the left carotid toward the innominate artery.

The number of the primary branches may be reduced to a single vessel, or more commonly two, the left carotid arising from the innominate artery, or (more rarely) the carotid and subclavian arteries of the left side arising from the innominate artery. But the number may be increased to four, from the right carotid and subclavian arteries arising directly from the aorta, the innominate being absent. In most of these latter cases the right subclavian has been found to arise from the left end of the arch; in other cases it was the second or third branch given off instead of the first. Another common form in which there are four primary branches is that in which the left vertebral artery arises from the arch of the aorta between the left carotid and subclavian arteries. Lastly, the number of trunks from the arch may be increased to five or six; in these instances, the external and internal carotids arise separately from the arch, the common carotid being absent on one or both sides. In some cases six branches have been found, and this condition is associated with the origin of both vertebral arteries from the arch.

Number Usual, Arrangement Different.—When the aorta arches over to the right side, the three branches have an arrangement the reverse of that which is usual. the innominate sup-

plying the left side, and the carotid and subclavian (which arise separately) the right side. In other cases, where the aorta takes its usual course, the two carotids may be joined in a common trunk, and the subclavians arise separately from the arch, the right subclavian generally arising from the left end of the arch.

In some instances other arteries are found to arise from the arch of the aorta. Of these the most common are the bronchial, one or both, and the thyroidea ima; also the internal mammary and the inferior thyroid have been seen to arise from this part of the vessel.

The Innominate Artery (*A. Anonyma*) (Figs. 432 and 433).

The **innominate** or **brachiocephalic** artery is the largest branch given off from the arch of the aorta. It *arises*, on a level with the upper border of the second right costal cartilage, from the commencement of the arch of the aorta in front of the left carotid, and, ascending obliquely to the upper border of the right sternoclavicular articulation, divides into the right common carotid and right subclavian arteries. This vessel varies from an inch and a half to two inches in length.

Relations.—*In front*, it is separated from the first piece of the sternum by the Sternohyoid and Sternothyroid muscles, the remains of the thymus gland, the left innominate and right inferior thyroid veins which cross its root, and sometimes the inferior cervical cardiac branch of the right vagus. *Behind*, it lies upon the trachea, which it crosses obliquely, and continuing upward it lies in the right pleura. On the *right side* is the right innominate vein, right vagus nerve, and the pleura; and on the *left side*, the remains of the thymus gland, the origin of the left carotid artery, the left inferior thyroid vein, and the trachea.

PLAN OF THE RELATIONS OF THE INNOMINATE ARTERY.

Behind.

Trachea.
Right pleura.

Branches.—The innominate usually gives off no branches, but occasionally a small branch, the **thyroidea ima**, is given off from this vessel. It also sometimes gives off a **thymic** or **bronchial branch**.

The **thyroidea ima** (*a. thyroidea ima*), which is occasionally present, ascends in front of the trachea to the lower part of the thyroid body, which it supplies. It varies greatly in size, and appears to compensate for the deficiency or absence of one of the other thyroid vessels. It occasionally is found to arise from the right common carotid or from the aorta, the subclavian, or internal mammary vessels.

Applied Anatomy.—Ligation of the innominate artery is an extremely grave operation. This was first done by Mott. The “operation of choice” seems to be that done by Burrell. “An incision is made at the anterior edge of the right Sternomastoid muscle, extending from the level of the cricoid cartilage to two inches below the upper border of the sternum. From this point another incision, extending outward four inches in length to the junction (right) of the outer

and middle thirds of the clavicle. The skin flap with the fascia and Platysma muscle is turned back. The Sternomastoid is severed close to its insertion into clavicle and sternum. The Sternothyroid, Sternohyoid, and Omohyoid are also divided." The sternoclavicular joint and the right side of the manubrium are honeycombed by means of a surgical engine or trephine. A flat retractor is slid underneath the joint while the trephining is done to protect the underlying parts. The block of bone is now removed. The right and left innominate veins going down to form the superior vena cava, with the vagus and right recurrent laryngeal nerves resting on the innominate artery, are all plainly to be seen. The sheath of the innominate artery is now opened and a ligature is applied. Burrell states that the exposure which is given by the removal of a part of the sternum is extremely satisfactory, and he fails to understand how a ligature can be applied to the innominate artery with any safety without a clear view of the anatomical structures involved.

Peculiarities in Point of Division.—When the bifurcation of the innominate artery varies from the point above mentioned it sometimes ascends a considerable distance above the sternal end of the clavicle; less frequently it divides below it. In the former class of cases its length may exceed two inches, and in the latter be reduced to an inch or less. These are points of considerable interest for the surgeon to remember in connection with the operation of tying this vessel.

Position.—When the aorta arches over to the right side, the innominate is directed to the left side of the neck instead of the right.

Collateral Circulation.—Allan Burns demonstrated, on the dead subject, the possibility of the establishment of the collateral circulation after ligation of the innominate artery, by tying and dividing that artery, after which, he says, "Even coarse injection, impelled into the aorta, passes freely by the anastomosing branches into the arteries of the right arm, filling them and all the vessels of the head completely."¹ The branches by which this circulation would be carried on are very numerous; thus, all the communications across the middle line between the branches of the carotid arteries of opposite sides would be available for the supply of blood to the right side of the head and neck; while anastomosis between the superior intercostal of the subclavian and the first aortic intercostal (see *infra* on the collateral circulation after obliteration of the thoracic aorta) would bring the blood, by a free and direct course, into the right subclavian; the numerous connections, also, between the intercostal arteries and the branches of the axillary and internal mammary arteries would, doubtless, assist in the supply of blood to the right arm, while the deep epigastric, from the external iliac, would, by means of its anastomosis with the internal mammary, compensate for any deficiency in the vascularity of the wall of the thorax.

ARTERIES OF THE HEAD AND NECK.

The chief artery which supplies the head and neck on each side is the **common carotid**; it ascends in the neck and divides into two branches: (1) The external carotid, supplying the superficial parts of the head and face and the greater part of the neck; (2) the internal carotid, supplying to a great extent the parts within the cranial cavity.

THE COMMON CAROTID ARTERY (*A. CAROTIS COMMUNIS*) (Figs. 431, 432).

The common carotid arteries differ in length and in their mode of origin. The right common carotid (*a. carotis communis dextra*) begins at the bifurcation of the innominate artery, behind the right sternoclavicular articulation, and is confined to the neck. The left common carotid (*a. carotis communis sinistra*) arises from the highest part of the arch of the aorta to the left of and on a plane posterior to the innominate artery, and therefore consists of a thoracic and a cervical portion.

The thoracic portion of the left common carotid artery ascends from the arch of the aorta through the superior mediastinum to the level of the left sternoclavicular joint, where it continues as the cervical portion.

Relations.—*In front*, it is separated from the first piece of the sternum by the Sternohyoid and Sternothyroid muscles, the anterior portions of the left pleura and lung, the left innominate vein, and the remains of the thymus gland; *behind*, it lies on the trachea, œsophagus, thoracic

¹ Surgical Anatomy of the Head and Neck, p. 62.

duct, and the left recurrent laryngeal nerve. To its *right side*, it is in relation with the innominate artery, inferior thyroid veins, and remains of the thymus gland. To its *left side*, with the left vagus nerve, left pleura, and left lung. The left subclavian artery is posterior and slightly external to it.

The **cervical portions** of the two common carotids resemble each other so closely that one description will apply to both. Each vessel passes obliquely upward from behind the sternoclavicular articulation to a level with the upper border of the thyroid cartilage, opposite the fourth cervical vertebra, where it divides into the **external** and **internal carotid arteries**.

At the lower part of the neck the two common carotid arteries are separated from each other by a small interval, which contains the trachea; but at the upper part, the thyroid body, the larynx, and pharynx project forward between the two vessels, and give the appearance of their being placed farther back in this situation. The common carotid artery is contained in a sheath derived from the deep cervical fascia, which also encloses the internal jugular vein and vagus nerve, the vein lying on the outer side of the artery, and the nerve between the artery and vein, on a plane posterior to both. On opening the sheath these three structures are seen to be separated from one another, each being enclosed in a separate fibrous investment.

Relations.—At the lower part of the neck the common carotid artery is very deeply seated, being covered by the integument, superficial fascia, Platysma, and deep cervical fascia, the Sternomastoid, Sternohyoid, and Sternothyroid muscles, and by the Omohyoid, opposite the cricoid cartilage; but in the upper part of its course, near its termination, it is more superficial, being covered merely by the integument, the superficial fascia, Platysma, deep cervical fascia, and inner margin of the Sternomastoid, and, when the latter is drawn backward, it is seen to be contained in a triangular space, bounded behind by the Sternomastoid, above by the posterior belly of the Digastric, and below by the anterior belly of the Omohyoid. This part of the artery is crossed obliquely, from within outward, by the sternomastoid artery; it is crossed also by the superior and middle thyroid veins, which terminate in the internal jugular; and, descending on its sheath in front, is seen the descendens hypoglossi nerve, this filament being joined by one or two branches from the cervical nerves, which cross the vessel from without inward. Sometimes the descendens hypoglossi is contained within the sheath. The middle thyroid vein crosses the artery about its middle, and the anterior jugular vein below; the latter, however, is separated from the artery by the Sternohyoid and Sternothyroid muscles. *Behind*, the artery is separated from the transverse processes of the vertebræ by the Longus colli and

PLAN OF THE RELATIONS OF THE COMMON CAROTID ARTERY.

On the posterior aspect of the angle of bifurcation of the common carotid is a reddish-brown oval body known as the **carotid gland**. (See Ductless Glands.)

Peculiarities as to Origin.—The *right common carotid* may arise above or below the upper border of the sternoclavicular articulation. This variation occurs in one out of about eight cases and a half, and the origin is more frequently below than above; or the artery may arise as a separate branch from the arch of the aorta or in conjunction with the left carotid. The *left common carotid* varies more frequently in its origin than the right. In the majority of abnormal cases it arises with the innominate artery, or, if the innominate artery is absent, the two carotids arise usually by a single trunk. It rarely joins with the left subclavian, except in cases of transposition of the arch.

Peculiarities as to Point of Division.—In the majority of abnormal cases this occurs higher than usual, the artery dividing into two branches opposite the hyoid bone, or even higher; more rarely it occurs below, opposite the middle of the larynx or the lower border of the cricoid cartilage; and one case is related by Morgagni where the common carotid, only an inch and a half in length, divided at the root of the neck. Very rarely the common carotid ascends in the neck without any subdivision, the internal carotid being wanting; and in a few cases the common carotid has been found to be absent, the external and internal carotids arising directly from the arch of the aorta. This peculiarity existed on both sides in some instances, on one side in others.

Occasional Branches.—Each common carotid usually gives off no branch previous to its bifurcation; but it occasionally gives origin to the superior thyroid or its laryngeal branch, the ascending pharyngeal, the inferior thyroid, or, more rarely, the vertebral artery.

Surface Marking.—The course of each common carotid artery is indicated by a line drawn from the sternal end of the clavicle below, to a point midway between the angle of the mandible and the mastoid process above. That portion of the line below the level of the upper border of the thyroid cartilage would represent the course of the vessel.

Applied Anatomy.—The operation of tying the common carotid artery may be necessary in a case of wound of that vessel or its branches, in aneurism, or in a case of pulsating tumor of the orbit or skull. If the wound involves the trunk of the common carotid, it will be necessary to tie the artery through the wound above and below the wounded part. If the wound is too small to admit of safe and rapid work it must be enlarged. In cases of aneurism, or where one of the branches of the common carotid is wounded in an inaccessible situation, it may be judged necessary to tie the trunk. In such cases the whole of the artery is accessible, and any part may be tied except close to either end. When the case is such as to allow of a choice being made, the lower part of the carotid should never be selected as the spot upon which to place a ligature, for not only is the artery in this situation placed very deeply in the neck, but it is covered by three layers of muscles, and, on the left side, in the great majority of cases, the internal jugular vein passes obliquely in front of it. Neither should the upper end be selected, for here the superior thyroid vein and its tributaries would give rise to very considerable difficulty in the application of a ligature. The point most favorable for the operation is that part of the vessel which is at the level of the cricoid cartilage. It occasionally happens that the carotid artery bifurcates

below its usual position; if the artery be exposed at its point of bifurcation, both divisions of the vessel should be tied near their origin, in preference to tying the trunk of the artery near its termination; and if, in consequence of the entire absence of the common carotid or from its early division, two arteries, the external and internal carotids, are met with, the ligature should be placed on that vessel which is found on compression to be connected with the diseased area.

Ligation of the Carotid at the Level of the Cricoid Cartilage (*Ligation in the Triangle of Election*).¹—The triangle of election is bounded posteriorly by the anterior edge of the Sternomastoid; is bounded above by the posterior belly of the Digastric; is bounded below by the anterior belly of the Omohyoid. In this operation the direction of the vessel and the inner margin of the Sternomastoid are the chief guides to its performance. The patient should be placed on his back with the head thrown back and turned slightly to the opposite side; an incision is to be made, three inches long, in the direction of the anterior border of the Sternomastoid, so that the centre corresponds to the level of the cricoid cartilage; after dividing the integument, superficial fascia, and Platysma, the deep fascia must be cut through on a director, so as to avoid wounding numerous small veins that are usually found beneath. The head may now be brought forward so as to relax the parts somewhat, and the margins of the wound are held asunder by retractors. The descendens hypoglossi nerve may now be exposed, and must be avoided, and, the sheath of the vessel having been raised by forceps, is to be opened to a small extent over the artery at its inner side. The internal jugular vein may present itself alternately distended and relaxed; this should be compressed both above and below, and drawn outward, in order to facilitate the operation. The aneurism needle is passed from the outside, care being taken to keep the needle in close contact with the artery, and thus avoid the risk of injuring the internal jugular vein or including the vagus nerve. Before the ligature is tied it should be ascertained that nothing but the artery is included in it.

Ligation of the Common Carotid at the Lower Part of the Neck (*Ligation in the Triangle of Necessity*).¹—The triangle of necessity is bounded above by the anterior belly of the Omohyoid; is bounded behind by the anterior margin of the Sternomastoid; is bounded in front by the mid-line of the neck. This operation is sometimes required in cases of aneurism of the upper part of the carotid, especially if the sac is of large size. It is best performed by dividing the sternal origin of the Sternomastoid muscle, but may be done in some cases, if the aneurism is not of very large size, by an incision along the anterior border of the Sternomastoid, extending down to the sternoclavicular articulation, and by then retracting the muscle. The easiest and best plan, however, is to make an incision two or three inches long down the lower part of the anterior border of the Sternomastoid muscle to the sternoclavicular joint, and a second incision, starting from the termination of the first, along the upper border of the clavicle for about two inches. This incision is made through the superficial and deep fascia, and the sternal origin of the muscle is exposed. This is to be divided on a director, and turned up, with the superficial structures, as a triangular flap. Some loose connective tissue is to be divided or torn through, and the outer border of the Sternohyoid muscle exposed. In doing this care must be taken not to wound the anterior jugular vein, which crosses the muscle to reach the external jugular or subclavian vein. The Sternohyoid, and with it the Sternothyroid, are to be drawn inward by means of a retractor, and the sheath of the vessel is exposed. This must be opened with great care on its inner or tracheal side, so as to avoid the internal jugular vein. This is especially necessary on the left side, where the artery is commonly overlapped by the vein. On the right side there is usually an interval between the artery and the vein, and not the same risk of wounding the latter.

The common carotid artery, being a long vessel without any branches, is particularly suitable for the performance of Brasdor's operation for the cure of an aneurism of the lower part of the vessel. Brasdor's procedure consists in ligating the artery on the distal side of the aneurism, and in the case of the common carotid there are no branches given off from the vessel between the aneurism and the site of the ligature; hence, the flow of blood through the sac of the aneurism is diminished, and cure takes place in the usual way, by the deposit of laminated fibrin.

Collateral Circulation.—After ligation of the common carotid the collateral circulation can be perfectly established by the free communication which exists between the carotid arteries of opposite sides, both without and within the cranium, and by enlargement of the branches of the subclavian artery on the side corresponding to that on which the vessel has been tied—the chief communication outside the skull taking place between the superior thyroid from the external carotid and the inferior thyroid from the subclavian, the profunda cervicis from the subclavian and the superior intercostal with the arteria princeps cervicis of the occipital; the vertebral taking the place of the internal carotid within the cranium.

¹ For description of the triangles of the neck, see page 605.

The External Carotid Artery (A. Carotis Externa) (Figs. 437, 438).

The **external carotid artery** commences opposite the upper border of the thyroid cartilage, and, taking a slightly curved course, passes upward and forward, and then inclines backward to the space between the neck of the condyle of the mandible and the external meatus; where it divides into the superficial temporal and internal maxillary arteries. It rapidly diminishes in size in its course up the neck, owing to the number and large size of the branches given off from it. In the child it is somewhat smaller than the internal carotid, but in the adult the two vessels are of nearly equal size. At its origin this artery is more superficial and placed nearer the middle line than the internal carotid, and is contained in the triangular space bounded by the Sternomastoid behind, the anterior belly of the Omohyoid below, and the posterior belly of the Digastric and the Stylohyoid above (*i. e.*, the superior carotid triangle).

Relations.—It is covered by the skin, superficial fascia, Platysma, deep fascia, and anterior margin of the Sternomastoid, and is crossed by the hypoglossal nerve, and by the lingual and facial veins; it is afterward crossed by the Digastric and Stylohyoid muscles, and higher up passes deeply into the substance of the parotid gland, where it lies beneath the facial nerve and the junction of the temporal and internal maxillary veins. *Internally* is the hyoid bone, wall of the pharynx, the superior laryngeal nerve, and the ramus of the mandible, from which it is separated by a portion of the parotid gland. *Externally*, in the lower part of its course, is the internal carotid artery. *Behind* it, near its origin, is the superior laryngeal nerve; and higher up, it is separated from the internal carotid by the Styloglossus and Stylopharyngeus muscles, the glossopharyngeal nerve, and part of the parotid gland.

Surface Marking.—The position of the external carotid artery may be marked out with sufficient accuracy by a line drawn from the front of the meatus of the external ear to the side of the cricoid cartilage, slightly arching the median line.

Applied Anatomy.—The application of a ligature to the external carotid may be required in case of wounds of this vessel, or of its branches when these cannot be tied, and in some cases of pulsating tumor of the scalp or face. The operation has not received the attention which it

deserves, owing to the fear which surgeons have entertained of secondary hemorrhage, on account of the number of branches given off from the vessel. This fear, however, has been shown by Mr. Cripps not to be well founded.¹ Ligation is often very useful as a means of preventing excessive hemorrhage in operations about the face, jaws, and mouth. It is sometimes employed with the hope of lessening the growth of tumors by cutting off the blood supply, but ligation is useless for this purpose. Ligation of one external carotid artery arrests the circulation for only a brief period, and within a very few days the circulation is practically freely reëstablished. This result is seen to be inevitable when we recall the numerous branches of the external carotid, their free anastomoses, and the fact that a very great number of extremely minute vessels in the middle line join the external carotid system of one side to that of the other side. Robert H. M. Dawbarn points out that ligation of both external carotids produces only temporary anemia, for "inside of a week or ten days thereafter the pulse can again be felt in the temporals and facials upon both sides." Dawbarn points out that even after excision of the external carotids, with separate ligation of each of the eight branches, blood can still reach the nose, tongue, etc., from outside systems by twenty-nine distinct routes. Whereas ligation of even both carotids will not prevent the growth of a malignant tumor, excision of each external carotid, with separate control of its eight branches, will sometimes prove of great value in retarding the progress of a growth. It "starves" the growth and may cause it to shrink (Dawbarn's operation). To tie the external carotid near its origin, below the point where it is crossed by the Digastric, an incision about three inches in length should be made along the margin of the Sternomastoid, from the angle of the mandible to the upper border of the thyroid cartilage. The ligature should be applied between the lingual and superior thyroid branches. To tie the vessel above the Digastric, between it and the parotid gland, an incision should be made, from the lobe of the ear to the greater cornu of the hyoid bone, dividing successively the skin, Platysma, and fascia. By drawing the Sternomastoid outward, the posterior belly of the Digastric and Stylohyoid muscles downward, and separating them from the parotid gland, the vessel will be exposed, and a ligature may be applied to it. The circulation is at once reëstablished by the free communication between most of the large branches of the artery (facial, lingual, superior thyroid, occipital) and the corresponding arteries of the opposite side and by the anastomosis of its branches with those of the internal carotid, and of the occipital with the branches of the subclavian, etc.

Branches.—The external carotid artery gives off eight branches, which, for convenience of description, may be divided into four sets. (See Fig. 439, Plan of the Branches.)

<i>Anterior.</i>	<i>Posterior.</i>	<i>Ascending.</i>	<i>Terminal.</i>
Superior Thyroid.	Occipital.	Ascending Pharyngeal.	Superficial Temporal.
Lingual.	Posterior Auricular.		Internal Maxillary.
Facial.			

The student is here reminded that many variations are met with in the number, origin, and course of these branches in different subjects; but the above arrangement is that which is found in the great majority of cases.

1. The **superior thyroid artery** (*a. thyroidea superior*) (Figs. 438 and 439) arises from the external carotid artery, just below the greater cornu of the hyoid bone, and terminates in the thyroid gland.

Relations.—From its origin under the anterior border of the Sternomastoid it runs upward and forward for a short distance in the superior carotid triangle, where it is covered by the integument, fascia, and Platysma; it then arches downward and forward beneath the Omohyoid, Sternohyoid, and Sternothyroid muscles. To the inner side are the Inferior constrictor of the pharynx and the external branch of the laryngeal nerve. It distributes numerous branches to the upper part of the gland, anastomosing with its fellow of the opposite side and with the inferior thyroid arteries. The terminal branches supplying the gland are generally two in number; one, the largest, the **anterior branch** (*ramus anterior*), descends at the anterior border of the lateral lobe of the gland, reaches the upper border of the isthmus, and then passes in the substance of the isthmus to the middle line of the neck, where it anastomoses with the corresponding artery of the opposite side; the **posterior branch** (*ramus posterior*) descends along

¹ Med.-Chir. Trans., lxi, 229.

² The Treatment of Certain Malignant Growths.

the posterior border of the lateral lobe of the gland, the anterior and posterior branches anastomose with each other and with branches of the inferior thyroid, and both of them send branches to the thyroid gland (*rami glandulares*). Besides the arteries distributed to the muscles by which it is covered and to the substance of the gland, the branches of the superior thyroid are the following:

Infrahyoid.
Sternomastoid.

Superior Laryngeal.
Cricothyroid.

The **infrahyoid branch** (*ramus hyoideus*) is small, and runs along the lower border of the hyoid bone beneath the Thyrohyoid muscle; after supplying the muscles connected to that bone, it forms an arch, by anastomosing with the vessel of the opposite side.

The **sternomastoid branch** (*ramus sternocleidomastoideus*) runs downward and outward across the sheath of the common carotid artery, and supplies the Sternomastoid and neighboring muscles and integument. There is frequently a separate branch from the external carotid distributed to the Sternomastoid muscle.

The **superior laryngeal** (*a. laryngea superior*), larger than either of the preceding, accompanies the internal branch of the superior laryngeal nerve, beneath the Thyrohyoid muscle; it pierces the thyrohyoid membrane, and supplies the muscles, mucous membrane, and glands of the larynx, anastomosing with the branch from the opposite side.

The **cricothyroid** (*ramus cricothyreoideus*) is a small branch which runs transversely across the cricothyroid membrane, and communicates with the artery of the opposite side.

Applied Anatomy. — The superior thyroid, or one of its branches, is often divided in cases of cut throat, giving rise to considerable hemorrhage. In such cases the artery should be secured, the wound being enlarged for that purpose, if necessary. The operation may be easily performed, the position of the artery being very superficial, and the only structures of importance covering it being a few small veins. The superior and inferior thyroid arteries of the involved side are ligated before extirpating a goitrous lobe of the thyroid gland.

The position of the superficial descending branch is of importance in connection with the operation of ligation of the common carotid artery. It crosses and lies on the sheath of this vessel, and may be wounded in opening the sheath. The position of the cricothyroid branch should be remembered, as it may prove the source of troublesome hemorrhage during the operation of laryngotomy. In performing the operation of *quick laryngotomy* the cricothyroid membrane should be incised transversely in order to avoid this vessel.

2. The **lingual artery** (*a. lingualis*) (Figs. 438 and 439) arises from the external carotid between the superior thyroid and facial; it first runs obliquely upward and inward to the great cornu of the hyoid bone; it then curves downward and forward, forming a loop which is crossed by the hypoglossal nerve, and passing beneath the Digastric and Stylohyoid muscles, it runs horizontally forward, beneath the Hyoglossus, and finally, ascending almost perpendicularly to the tongue, turns forward on its under surface as far as the tip, under the name of the **ranine artery**.

FIG. 440.—Showing the relation of the lingual artery and hypoglossal nerve. *Lesser's triangle* is bounded above by the nerve, below by the posterior belly of the Digastric, and in front by the posterior border of the Mylohyoid, indicated by a solid line. The floor of the triangle is occupied by the Hyoglossus.

Relations.—Its *first*, or *oblique*, *portion* is superficial, being contained in the same triangular space as the superior thyroid artery, resting upon the Middle constrictor of the pharynx, and covered by the Platysma and fascia of the neck. Its *second*, or *curved*, *portion* also lies upon the Middle constrictor, being covered at first by the tendon of the Digastric and the Stylohyoid muscle, and afterward by the Hyoglossus, the latter muscle separating it from the hypoglossal nerve. Its *third*, or *horizontal*, *portion* lies between the Hyoglossus and Geniohyoglossus muscles. The *fourth*, or *terminal*, *part*, under the name of the *ranine*, runs along the under surface of the tongue to its tip; it is very superficial, being covered only by the mucous membrane, and rests on the Lingualis on the outer side of the Geniohyoglossus. The hypoglossal nerve crosses the lingual artery, and then becomes separated from it, in the second part of its course, by the Hyoglossus muscle.

Branches.—The branches of the lingual artery are the

Suprahyoid.
Dorsalis Linguae.

Sublingual.
Ranine.

The **suprahyoid branch** (*ramus hyoideus*) runs along the upper border of the hyoid bone, supplying the muscles attached to it and anastomosing with its fellow of the opposite side.

The **dorsalis linguae** (*ramus dorsalis linguae*) (Fig. 496) *arises* from the lingual artery beneath the Hyoglossus muscle; it ascends to the back of the dorsum of the tongue, and supplies the mucous membrane, the tonsil, soft palate, and epiglottis, anastomosing with its fellow from the opposite side. This artery is frequently represented by two or three small branches.

The **sublingual** (*a. sublingualis*), which may be described as a branch of bifurcation of the lingual artery, *arises* at the anterior margin of the Hyoglossus muscle, and runs forward between the Geniohyoglossus and the sublingual gland. It supplies the substance of the gland, giving branches to the Mylohyoid and neighboring muscles, the mucous membrane of the mouth and gums. One branch runs behind the alveolar process of the mandible in the substance of the gum to anastomose with a similar artery from the other side.

The **ranine**, or **deep lingual** (*a. profunda linguae*), may be regarded as the other branch of bifurcation. It is usually described as the continuation of the lingual artery; it runs along the under surface of the tongue, resting on the Inferior lingualis, and covered by the mucous membrane of the mouth; it lies on the outer side of the Geniohyoglossus, accompanied by the lingual nerve. On arriving at the tip of the tongue it is said to anastomose with the artery of the opposite side, but this is denied by Hyrtl. In the mouth these vessels are placed one on either side of the frenum.

Applied Anatomy.—The lingual artery may be divided near its origin in cases of *cut throat*, a complication that not infrequently happens in this class of wounds; or *severe hemorrhage* which cannot be restrained by ordinary means may ensue from a wound or deep ulcer of the tongue. In the former case the primary wound may be enlarged if necessary, and the bleeding vessels secured. In the latter case it has been suggested that the lingual artery should be tied near its origin. Ligation of the lingual artery is also occasionally practised, as a palliative measure, in cases of *cancer of the tongue*, in order to check the progress of the disease by starving the growth and it is often tied as a preliminary measure to *removal of the tongue*. The operation is a somewhat difficult one, on account of the depth of the artery, the number of important structures by which it is surrounded, the loose and yielding nature of the parts upon which it is supported, and its occasional irregularity of origin. An incision is to be made in a curved direction from a point one finger's breadth external to the symphysis of the mandible downward to the cornu of the hyoid bone, and then upward to near the angle of the mandible. Care must be taken not to carry this incision too far backward, for fear of endangering the facial vein. In the first incision the skin, superficial fascia, and Platysma will be divided, and the deep fascia exposed. The deep fascia is then to be incised, and the submaxillary gland exposed and pulled upward by retractors. A triangular space is now exposed, *Lesser's triangle* (Fig. 440), bounded internally by the posterior border of the Mylohyoid muscle; below and externally, by the tendon of the Digastric; and above, by the hypoglossal nerve. The floor of the space is formed by the

Hyoglossus muscle, beneath which the artery lies. The fibres of this muscle are now to be cut through horizontally and the vessel exposed, care being taken, while near the vessel, not to open the pharynx.

Troublesome hemorrhage may occur in the *division of the frenum* in children if the ranine arteries, which lie on each side of it, are wounded. The student should remember that the operation is always to be performed with a pair of blunt-pointed scissors, and the mucous membrane only is to be divided by a very superficial cut, which cannot endanger any vessel. The scissors, also, should be directed toward the floor of the mouth. Any further liberation of the tongue which may be necessary can be effected by tearing.

3. The **facial artery** (*a. maxillaris externa*) (Figs. 438 and 441) *arises* a little above the lingual, and passes obliquely upward, beneath the Digastric and Stylohyoid muscles, and frequently beneath the hypoglossal nerve; it now runs forward

FIG. 441.—The arteries of the face and scalp. The muscle tissue of the lips must be supposed to have been cut away, in order to show the course of the coronary arteries.

under cover of the body of the mandible, lodged in a groove on the posterior surface of the submaxillary gland; this may be called the **cervical part** of the artery. It then curves upward over the body of the mandible at the anterior inferior angle of the Masseter muscle; passes forward and upward across the cheek to the angle of the mouth, then upward along the side of the nose, and terminates at the inner canthus of the eye, under the name of the **angular artery**. The facial artery, both in the neck and on the face, is remarkably tortuous; in the former situation its tortuosity enables it to accommodate itself to the movements of the pharynx in deglutition, and in the latter to the movements of the mandible and the lips and cheeks.

Relations.—*In the neck* its origin is superficial, being covered by the integument, Platysma, and fascia; it then passes beneath the Digastric and Stylohyoid muscles and part of the submaxillary gland. It lies upon the Middle constrictor of the pharynx, and is separated from the Styloglossus and Hyoglossus muscles by a portion of the submaxillary gland. *On the face*, where it passes over the body of the mandible, it is comparatively superficial, lying immediately beneath the Platysma. In this situation its pulsation may be distinctly felt, and compression of the vessel against the bone can be effectually made. In its course over the face it is covered by the integument, the fat of the cheek, and, near the angle of the mouth, by the Platysma, Risorius, and Zygomatic muscles. It rests on the Buccinator, the Levator anguli oris, and the Levator labii superioris (sometimes piercing or else passing under this last muscle). The facial vein lies to the outer side of the artery, and takes a more direct course across the face, where it is separated from the artery by a considerable interval. In the neck it lies superficial to the artery. The branches of the facial nerve cross the artery, and branches of the infra-orbital nerve lie beneath it.

Branches.—The branches of this vessel may be divided into two sets—those given off below the mandible (*cervical*), and those on the face (*facial*).

Cervical Branches.

Ascending Palatine.
Tonsillar.
Submaxillary.
Submental.

Facial Branches.

Inferior labial.
Inferior labial coronary.
Superior labial coronary.
Lateral nasal.
Angular.
Muscular.

The **ascending palatine** (*a. palatine ascendens*) passes up between the Styloglossus and Stylopharyngeus to the outer side of the pharynx, along which it is continued between the Superior constrictor and the Internal pterygoid to near the base of the skull. It divides, near the Levator palati, into two branches; one follows the course of the Levator palati, and, winding over the upper border of the Superior constrictor, supplies the soft palate and the palatine glands, anastomosing with its fellow of the opposite side and with the posterior palatine branch of the internal maxillary artery; the other pierces the Superior constrictor and supplies the tonsil and Eustachian tube, anastomosing with the tonsillar and ascending pharyngeal arteries.

The **tonsillar branch** (*ramus tonsillaris*) passes up between the Internal pterygoid and Styloglossus, and then ascends along the side of the pharynx, perforating the Superior constrictor, to ramify in the substance of the tonsil and root of the tongue.

The **submaxillary or glandular branches** (*rami glandulares*) consist of three or four large vessels, which supply the submaxillary gland, some being prolonged to the neighboring muscles, lymph nodes, and integument.

The **submental** (*a. submentalis*) (Fig. 438), the largest of the cervical branches, is given off from the facial artery just as that vessel emerges from the submaxillary gland; it runs forward upon the Mylohyoid muscle, just below the body of the mandible and beneath the Digastric; after supplying the surrounding muscles, and anastomosing with the sublingual artery by branches which perforate the Mylohyoid muscle, it arrives at the symphysis of the mandible, where it turns over the border of the mandible and divides into a superficial and a deep branch; the former passes between the integument and Depressor labii inferioris, supplies both, and anastomoses with the inferior labial. The deep branch passes between the latter muscle and the bone, supplies the lip, and anastomoses with the inferior labial and mental arteries.

The **inferior labial** (*a. labialis inferior*) (Fig. 441) passes beneath the Depressor anguli oris, to supply the muscles and integument of the chin and lower lip, anastomosing with the inferior labial coronary and submental branches of the facial, and with the mental branch of the inferior dental artery.

The **inferior labial coronary** (Figs. 441 and 442) is derived from the facial artery, near the angle of the mouth; it passes upward and inward beneath the Depressor anguli oris, and, penetrating the Orbicularis oris muscle, runs in a tortuous course along the edge of the lower lip between this muscle and the mucous membrane, anastomoses with the artery of the opposite side. This artery supplies the labial glands, the mucous membrane, and muscles of the lower lip, and anastomoses with the inferior labial from the facial and the mental branch of the inferior dental artery.

The **superior labial coronary** (*a. labialis superior*) (Figs. 441 and 442) is larger and more tortuous in its course than the preceding. It follows the same course along the edge of the upper lip, lying between the mucous membrane and the Orbicularis oris, and anastomoses with the artery of the opposite side. It supplies the tissues of the upper lip, and gives off in its course two or three vessels which ascend to the nose. One, named the **inferior artery of the septum**, ramifies on the septum of the nostrils as far as the point of the nose; another, the **artery of the ala**, supplies the ala of the nose.

The **lateralis nasi** is derived from the facial, as that vessel is ascending along the side of the nose; it supplies the ala and dorsum of the nose, anastomosing with its fellow, the nasal branch of the ophthalmic, the inferior artery of the septum, the artery of the ala, and the infraorbital.

FIG. 442.—The labial coronary arteries, the glands of the lips, and the nerves of the right side seen from the posterior surface after removal of the mucous membrane. (Poirier and Charpy.)

The **angular artery** (*a. angularis*) is the termination of the trunk of the facial; it ascends to the inner angle of the orbit, embedded in the fibres of the Levator labii superioris alaeque nasi, and accompanied by a large vein, the **angular vein**; it distributes some branches on the cheek which anastomose with the infraorbital. After supplying the lacrimal sac and Orbicularis palpebrarum muscle, the angular artery terminates by anastomosing with the nasal branch of the ophthalmic artery.

The **muscular branches** are distributed to the Internal pterygoid and Stylohyoid in the neck, and to the Masseter and Buccinator on the face.

The anastomoses of the facial artery are very numerous, not only with the vessel of the opposite side, but, in the neck, with the sublingual branch of the lingual; with the ascending pharyngeal; and with the posterior palatine, a branch of the internal maxillary, by its ascending palatine and tonsillar branches; on the face, with the mental branch of the inferior dental as it emerges from the mental foramen, with the transverse facial, a branch of the temporal; with the infraorbital, a branch of the internal maxillary, and with the nasal branch of the ophthalmic.

Peculiarities.—The facial artery not infrequently arises by a common trunk with the lingual. This vessel is also subject to some variations in its size and in the extent to which it supplies the face. It occasionally terminates as the submental, and not infrequently supplies the face

only as high as the angle of the mouth or nose. The deficiency is then supplied by enlargement of one of the neighboring arteries.

Applied Anatomy.—The passage of the facial artery over the body of the mandible would appear to afford a favorable position for the application of pressure in case of hemorrhage from the lips, the result either of an accidental wound or during an operation; but its application is useless, except for a very short time, on account of the free communication of this vessel with its fellow and with numerous branches from different sources. In a *wound involving the lip* it is better to seize the part between the fingers, and evert it, when the bleeding vessel may be at once secured with pressure forceps. In order to *prevent hemorrhage* in cases of removal of diseased growths from the part, the lip should be compressed on each side between the fingers and thumb or by a pair of specially devised clamp forceps, while the surgeon excises the diseased part. In order to stop hemorrhage where the lip has been divided in an operation, it is necessary, in uniting the edges of the wound, to pass the sutures through the cut edges from the skin almost as deep as the mucous surface; by these means not only are the cut surfaces more neatly and securely adapted to each other, but the possibility of hemorrhage is prevented by including in the suture the divided artery. If the suture is, on the contrary, passed through merely the cutaneous portion of the wound, hemorrhage occurs into the cavity of the mouth. Lastly, the relation of the angular artery to the lacrimal sac should be observed, and it will be seen that, as the vessel passes up along the inner margin of the orbit, it ascends on the nasal side. In operating for *fistula lacrimalis* the sac should always be opened on its outer side, in order that this vessel may be avoided.

FIG. 443.—The loop of the hypoglossal nerve and the branches of the external carotid artery.

ascends in a tortuous course over the occiput, as high as the vertex, where it divides into numerous branches. It is accompanied in the latter part of its course by the great occipital nerve, and occasionally by a cutaneous filament from the suboccipital nerve.

Branches.—The branches given off from this vessel are:

Muscular.	Meningeal or dural.
Sternomastoid.	Mastoid.
Auricular.	Arteria princeps cervicis.

Cranial branches.

The **muscular branches** (*rami musculares*) supply the Digastric, Stylohyoid, Splenius, and Trachelomastoid muscles.

The **sternomastoid** (*a. sternocleidomastoidea*) is a large and constant branch, generally arising from the artery close to its commencement, but sometimes springing directly from the external carotid. It first passes downward and backward over the hypoglossal nerve, and enters the substance of the muscle in company with the spinal accessory nerve.

4. The **occipital artery** (*a. occipitalis*) (Figs. 438 and 443) arises from the posterior part of the external carotid, opposite the facial, near the lower margin of the Digastric muscle.

Relations.—At its origin it is covered by the posterior belly of the Digastric muscle and the Stylohyoid muscle, and the hypoglossal nerve winds around it from behind forward; higher up, it passes across the internal carotid artery, the internal jugular vein, and the vagus and spinal accessory nerves; it then ascends to the interval between the transverse process of the atlas and the mastoid process of the temporal bone, and passes horizontally backward in the occipital groove on the mastoid portion of the temporal, being covered by the Sternomastoid, Splenius, Trachelomastoid, and Digastric muscles, and resting upon the Rectus lateralis, the Superior oblique, and Complexus muscles; it then changes its course and passes vertically upward, pierces the fascia which connects the cranial attachment of the Trapezius with the Sternomastoid, and

The **auricular branch** (*ramus auricularis*) supplies the back part of the concha. It frequently gives off a branch, which enters the skull through the mastoid foramen and supplies the dura, the diploë, and the mastoid cells.

The **meningeal or dural branch** (*ramus meningeus*) ascends with the internal jugular vein, and enters the skull through the foramen lacerum posterius, or through the anterior condylar foramen, to supply the dura in the posterior fossa.

The **mastoid branch** (*ramus mastoideus*) is a small vessel, by no means constant. It passes into the skull through the mastoid foramen and is distributed upon the dura of the posterior fossa.

The **arteria princeps cervicis** (*ramus descendens*), the largest branch of the occipital, descends along the back part of the neck and divides into a superficial and a deep branch. The superficial branch runs beneath the Splenius, giving off branches which perforate that muscle to supply the Trapezius, and then anastomose with the superficial cervical artery, a branch of the transversalis colli; the deep branch passes beneath the Complexus between it and the Semispinalis colli, and anastomoses with branches from the vertebral and with the deep cervical artery, a branch of either the superior intercostal or the subclavian. The anastomosis between these vessels helps to establish the collateral circulation after ligation of the carotid or subclavian artery.

The **cranial branches** (*rami occipitales*) of the occipital artery are distributed upon the occiput; they are very tortuous, and lie between the integument and Occipitofrontalis, anastomosing with the artery of the opposite side, the posterior auricular and temporal arteries. They supply the back part of the Occipitofrontalis muscle, the integument, and pericranium.

5. The **posterior auricular artery** (*a. auricularis posterior*) (Figs. 439 and 441) is a small vessel which arises from the external carotid, above the Digastric and Stylohyoid muscles, opposite the apex of the styloid process. It ascends, under cover of the parotid gland, on the styloid process of the temporal bone, to the groove between the cartilage of the ear and the mastoid process, immediately above which it divides into its two terminal branches, the **auricular** and **mastoid**. Just before arriving at the mastoid process, this artery is crossed by the facial nerve, and has beneath it the spinal accessory nerve.

Branches.—Besides several small branches to the Digastric, Stylohyoid, and Sternomastoid muscles and to the parotid gland, this vessel gives off three branches:

Stylomastoid.

Auricular.

Mastoid.

The **stylomastoid branch** (*a. stylomastoidea*) enters the stylomastoid foramen, and supplies the tympanum, mastoid cells, and semicircular canals. In the young subject a branch from this vessel forms, with the tympanic branch from the internal maxillary, a vascular circle, which surrounds the tympanic membrane, and from which delicate vessels ramify on that membrane. It anastomoses with the petrosal branch of the middle meningeal artery by a twig, which enters the hiatus Fallopii.

The **auricular branch** (*ramus auricularis*), one of the terminal branches, ascends behind the ear, beneath the Retrahens aurem muscle, and is distributed to the back part of the cartilage of the ear, upon which it ramifies minutely, some branches curving around the margin of the fibrocartilage, others perforating it, to supply its anterior surface. It anastomoses with the posterior branch and also with the anterior auricular branches of the superficial temporal.

The **mastoid branch** (*ramus mastoideus*) passes backward, over the Sternomastoid muscle, to the scalp above and behind the ear. It supplies the posterior belly of the Occipitofrontalis muscles and the scalp in this situation. It anastomoses with the occipital artery.

6. The **ascending pharyngeal artery** (*a. pharyngea ascendens*) (Fig. 438 and 439), the smallest branch of the external carotid, is a long, slender vessel, deeply seated in the neck, beneath the other branches of the external carotid and the Stylopharyngeus muscle. It *arises* from the back part of the external carotid, near the commencement of that vessel, and ascends vertically between the internal carotid and the side of the pharynx, to the under surface of the base of the skull, lying on the Rectus capitis anticus major muscle.

Branches.—Its branches may be subdivided as follows:

Prevertebral.
Pharyngeal.

Palatine.
Tympanic.

Meningeal or dural.

The **prevertebral branches** are numerous small vessels which supply the Recti capitis antici and Longus colli muscles, the sympathetic, hypoglossal, and vagus nerves, and the lymph nodes. They anastomose with the ascending cervical artery, a branch of the inferior thyroid.

The **pharyngeal branches** (*rami pharyngei*) are three or four in number. Two of these descend to supply the Middle and Inferior constrictors and the Stylopharyngeus, ramifying in the substance of the muscles and in the submucous tissue of the mucous membrane lining them.

The **palatine branch** varies in size, and may take the place of the ascending palatine branch of the facial artery, when that vessel is small. It passes inward upon the Superior constrictor, and sends ramifications to the soft palate and tonsil, and supplies a branch to the Eustachian tube.

The **tympanic branch** (*a. tympanica inferior*) is a small artery which passes through a minute foramen in the petrous portion of the temporal bone, in company with the tympanic branch of the glossopharyngeal nerve to supply the inner wall of the tympanum and anastomose with the other tympanic arteries.

The **meningeal or dural branches** consist of several small vessels, which pass through foramina in the base of the skull, to supply the dura. One, the **posterior meningeal or postdural** (*a. meningea posterior*), enters the cranium through the foramen lacerum posterius; a second passes through the foramen lacerum medium; and occasionally a third through the anterior condylar foramen.

Applied Anatomy.—The ascending pharyngeal artery has been wounded from the throat, as in the case in which the stem of a tobacco-pipe was driven into the vessel, causing fatal hemorrhage. After removal of the tonsil there is sometimes severe bleeding. This is almost never due to wounding of the internal carotid artery, as the latter vessel, if normally placed, is too far away to be damaged. The bleeding comes from the branches of the ascending pharyngeal, tonsillar, or ascending palatine arteries.

7. The **superficial temporal artery** (*a. temporalis superficialis*) (Figs. 438 and 441), the smaller of the two terminal branches of the external carotid, appears, from its direction, to be the continuation of that vessel. It commences in the substance of the parotid gland, behind the neck of the mandible, and crosses over the posterior root of the zygoma, passes beneath the Attrahens aurem muscle, lying on the temporal fascia, and divides, about two inches above the zygomatic arch, into two branches, an **anterior** and a **posterior**. This vessel is accompanied by the auriculo-temporal nerve.

Relations.—The superficial temporary artery, as it crosses the zygoma, is covered by the Attrahens aurem muscle, and by a dense fascia given off from the parotid gland; it is crossed by the temporofacial division of the facial nerve and one or two veins, and is accompanied by the auriculotemporal nerve, which lies behind it.

Besides some twigs to the parotid gland, the articulation of the mandible, and the Masseter muscle, its branches are:

Transverse facial.	Anterior auricular.
Middle temporal.	Anterior temporal.
Orbital.	Posterior temporal.

The **transverse facial branch** (*a. transversa faciei*) is given off from the temporal before that vessel quits the parotid gland; running forward through its substance, it passes transversely across the face, between the parotid duct and the lower border of the zygoma, and divides on the side of the face into numerous branches, which supply the parotid gland, the Masseter muscle, and the integument, anastomosing with the facial, masseteric, and infraorbital arteries. This vessel rests on the Masseter, and is accompanied by one or two branches of the facial nerve. It is sometimes a branch of the external carotid.

The **middle temporal artery** (*a. temporalis media*) arises immediately above the zygomatic arch, and, perforating the temporal fascia, gives branches to the Temporal muscle, anastomosing with the deep temporal branches of the internal maxillary. It occasionally gives off an **orbital branch**, which runs along the upper border of the zygoma, between the two layers of the temporal fascia, to the outer angle of the orbit. This branch, which may arise directly from the superficial temporal artery, supplies the Orbicularis palpebrarum, and anastomoses with the lacrimal and palpebral branches of the ophthalmic artery.

The **orbital artery** (*a. zygomaticoorbitalis*) comes off from the temporal just above the zygoma and is distributed to the upper orbital margin.

The **anterior auricular branches** (*rami auriculares anteriores*) are distributed to the anterior portion of the pinna, the lobule, and part of the external meatus, anastomosing with branches of the posterior auricular.

The **anterior temporal** runs tortuously upward and forward, to the forehead, supplying the muscles, integument, and pericranium in this region, and anastomoses with the supraorbital and frontal arteries. The terminal portion of the anterior branch is called the **frontal artery** (*ramus frontalis*).

The **posterior temporal**, larger than the anterior, curves upward and backward along the side of the head, lying superficial to the temporal fascia, and inosculates with its fellow of the opposite side, and with the posterior auricular and occipital arteries. The terminal portion of the posterior branch is named the **parietal artery** (*ramus parietalis*).

Applied Anatomy.—The temporal artery, as it crosses the zygoma, lies immediately beneath the skin, and its pulsations may be readily felt during the administration of an anesthetic, or under circumstances where the radial pulse is not available; or it may be easily compressed against the bone in order to check bleeding from the temporal region of the scalp. When a flap is raised from this part of the head, as in the operation of trephining, the incision should be shaped like a horseshoe, with its convexity upward, so that the flap shall contain the temporal artery which insures a sufficient supply of blood. The same principle is applied, as far as possible, in making incisions to raise flaps in other parts of the scalp.

8. The **internal maxillary artery** (*a. maxillaris interna*) (Figs. 444 and 445), the larger of the two terminal branches of the external carotid, *arises* behind the neck of the mandible, and is at first embedded in the substance of the parotid gland; it passes inward between the ramus of the mandible and the internal lateral ligament, and then upon the outer surface of the External pterygoid muscle to the sphenomaxillary fossa to supply the deep structures of the face. For convenience of description it is divided into three portions—a **maxillary**, a **pterygoid**, and a **sphenomaxillary**.

The **first or maxillary portion** passes horizontally forward and inward, between the ramus of the mandible and the internal lateral ligament, where it lies parallel

to and a little below the auriculotemporal nerve; it crosses the inferior dental nerve, and lies along the lower border of the External pterygoid muscle.

The **second or pterygoid portion** runs obliquely forward and upward under cover of the ramus of the mandible, on the outer (very frequently on the inner) surface of the External pterygoid muscle; it then passes between the two heads of origin of this muscle and enters the sphenomaxillary fossa.

FIG. 444.—The internal maxillary artery and its branches.

FIG. 445.—Plan of the branches of the internal maxillary artery.

The **third or sphenomaxillary portion** lies in relation with Meckel's ganglion. The branches of this vessel may be divided into three groups, corresponding with its three divisions.

Branches of the maxillary portion (Fig. 445):

Anterior tympanic.
Deep auricular.

Middle meningeal or Medidural.
Small meningeal or Parvidural.
Inferior dental.

The **anterior tympanic branch** (*a. tympanica anterior*) passes upward behind the articulation of the mandible, enters the tympanum through the Glaserian fissure, and ramifies upon the membrana tympani, forming a vascular circle around the membrane with the stylomastoid artery, and anastomosing with the Vidian and the tympanic branch from the internal carotid.

The **deep auricular branch** (*a. auricularis profunda*) often arises in common with the preceding. It ascends in the substance of the parotid gland, behind the temporomaxillary articulation, pierces the cartilaginous or bony wall of the external auditory meatus, and supplies its cuticular lining and the outer surface of the tympanic membrane. It gives a branch to the temporomandibular joint.

The **middle meningeal or medidural branch** (*a. meningea media, a. mediduralis*) is the largest of the branches which supply the dura. It ascends between the internal lateral ligament and the neck of the mandible, and passes vertically upward between the two roots of the auriculotemporal nerve to the foramen spinosum of the sphenoid bone, through which it enters the cranium; it then runs upward and forward in a groove on the greater wing of the sphenoid bone and divides into two branches, anterior and posterior. The **anterior branch**, the larger, crosses the greater wing of the sphenoid, and reaches the groove, or canal, in the antero-inferior angle of the parietal bone, and then divides into two branches which spread out between the dura and internal surface of the cranium, some passing upward as far as the vertex, and others backward to the occipital region. The **posterior branch** crosses the squamous portion of the temporal, and on the inner surface of the parietal bone divides into branches which supply the posterior part of the dura and cranium. The branches of this vessel are distributed partly to the dura, but chiefly to the bones; they anastomose with the arteries of the opposite side, and with the anterior and posterior meningeal arteries.

The middle meningeal on entering the cranium gives off the following collateral branches: (1) Numerous small vessels to the Gasserian ganglion, and to the dura in this situation. (2) A branch, the **petrosal branch** (*ramus petrosus superficialis*), which enters the hiatus Fallopii, supplies the facial nerve, and anastomoses with the stylomastoid branch of the posterior auricular artery. (3) A minute **superior tympanic branch** (*a. tympanica superior*), which runs in the canal for the Tensor tympani muscle, and supplies this muscle and the lining membrane of the canal. (4) **Orbital branches**, which pass through the sphenoidal fissure, or through separate canals in the greater wing of the sphenoid to anastomose with the lacrimal or other branches of the ophthalmic artery. (5) **Temporal or anastomotic branches**, which pass through the foramina in the greater wing of the sphenoid bone and anastomose in the temporal fossa with the deep temporal arteries.

Applied Anatomy.—The middle meningeal is an artery of considerable surgical importance, as it may be injured in *fractures of the temporal region* of the skull. The vessel may be ruptured by traumatism, even though the skull escape fracture. *Rupture of the middle meningeal artery* will be followed by considerable hemorrhage between the bone and dura, which may cause compression of the brain and require the operation of trephining for its relief. This artery crosses the anterior inferior angle of the parietal bone at a point $1\frac{1}{2}$ inches (3.75 cm.) behind the external angular process of the frontal bone, and $1\frac{3}{4}$ inches (4.5 cm.) above the zygoma. From this point the anterior branch passes upward and slightly backward to the sagittal suture, lying about $\frac{1}{2}$ inch (12 mm.) to $\frac{3}{4}$ inch (18 mm.) behind the coronal suture. The posterior branch passes upward and backward over the squamous portion of the temporal bone. In order to expose the artery as it lies in the groove in the parietal bone, a semilunar incision, with its convexity upward, should be made, commencing an inch behind the external angular process, and carried backward for two inches. The structures cut through are: (1) Skin; (2) superficial fascia, with branches of the superficial temporal vessels and nerves; (3) the fascia continued down from the aponeurosis of the Occipitofrontalis; (4) the two layers of the temporal fascia; (5) the Temporal muscle; (6) the deep temporal vessels; (7) the pericranium. The bone is trephined, the clot removed, and the vessel secured by ligatures, suture ligatures, or gauze packing.

The **small meningeal or parvidural branch** (*ramus meningeus accessorius, parviduralis*) is sometimes derived from the preceding. It enters the skull through the foramen ovale, and supplies the Gasserian ganglion and dura.

The **inferior dental branch** (*a. alveolaris inferior*) descends with the inferior dental nerve to the foramen on the inner side of the ramus of the mandible. It runs along the *dental canal* in the substance of the bone, accompanied by the nerve, and opposite the first bicuspid tooth divides into two branches, the **incisor** and **mental**; the **incisor branch** is continued forward beneath the incisor teeth as far as the symphysis, where it anastomoses with the artery of the opposite side; the **mental branch** (*a. mentalis*) escapes with the nerve at the mental foramen, supplies the structures composing the chin, and anastomoses with the submental, inferior labial, and inferior coronary arteries. Near its origin the inferior dental artery gives off a **lingual branch**, which descends with the lingual nerve and supplies the mucous membrane of the mouth. As the inferior dental artery enters the foramen it gives off a **mylohyoid branch** (*ramus mylohyoideus*), which runs in the mylohyoid groove, and ramifies on the under surface of the Mylohyoid muscle. The inferior dental artery and its incisor branches during their course through the substance of the bone give off a few twigs which are lost in the cancellous tissue, and a series of branches which correspond in number to the roots of the teeth; these enter the minute apertures at the extremities of the fangs and supply the pulp of the teeth.

Branches of the pterygoid portion (Fig. 445):

Deep temporal.
Pterygoid.

Masseteric.
Buccal.

These branches are distributed, as their names imply, to the muscles in the maxillary region.

The **deep temporal branches**, two in number, **anterior** (*a. temporalis profunda anterior*) and **posterior** (*a. temporalis profunda posterior*), each occupy that part of the temporal fossa indicated by its name. Ascending between the Temporal muscle and pericranium, they supply the muscle and anastomose with the middle temporal artery. The anterior branch communicates with the lacrimal artery by means of small branches which perforate the malar bone and greater wing of the sphenoid.

The **pterygoid branches** (*rami pterygoidei*), irregular in their number and origin, supply the Pterygoid muscles.

The **masseteric** (*a. masseterica*) is a small branch which passes outward, above the sigmoid notch of the mandible, to the deep surface of the Masseter muscle. It supplies that muscle, and anastomoses with the masseteric branches of the facial and with the transverse facial artery.

The **buccal** (*a. buccinatoria*) is a small branch which runs obliquely forward between the Internal pterygoid and the ramus of the mandible, to the outer surface of the Buccinator, to which it is distributed, anastomosing with branches of the facial artery.

Branches of the sphenomaxillary portion (Fig. 445):

Alveolar or Posterior dental.
Infraorbital.
Descending palatine.

Vidian.
Pterygopalatine.
Naso- or sphenopalatine.

The **alveolar or posterior dental branch** (*a. alveolaris superior posterior*) is given off from the internal maxillary in conjunction with the infraorbital, and just as the trunk of the vessel is passing into the sphenomaxillary fossa. Descending upon the tuberosity of the maxilla, it divides into numerous branches, some of which enter the posterior dental canals, to supply the upper molar and bicuspid teeth and the lining of the antrum, while others are continued forward on the alveolar process to supply the gums.

The **infraorbital** (*a. infraorbitalis*) appears, from its direction, to be the continuation of the trunk of the internal maxillary, but often it *arises* from that vessel in conjunction with the preceding branch. It runs along the infraorbital canal with the superior maxillary nerve, and emerges upon the face at the infraorbital foramen, beneath the Levator labii superioris muscle. While in the canal, it gives off (*a*) branches which ascend into the orbit, and assist in supplying the Inferior rectus and Inferior oblique muscles and the lacrimal gland, and (*b*) the **anterior dental branches** (*aa. alveolares superiores anteriores*), which descend through the anterior dental canals in the bone to supply the mucous membrane of the antrum and the front teeth of the maxilla. On the face, some branches pass upward to the inner angle of the orbit and the lacrimal sac, anastomosing with the angular branch of the facial artery; others run inward toward the nose, anastomosing with the nasal branch of the ophthalmic; and others descend beneath the Levator labii superioris muscle, and anastomose with the transverse facial and buccal arteries.

The four remaining branches arise from that portion of the internal maxillary which is contained in the sphenomaxillary fossa.

The **descending palatine** (*a. palatina descendens*) descends through the posterior palatine canal with the anterior palatine branch of the sphenopalatine (Meckel's) ganglion, and, emerging from the posterior palatine foramen, runs forward in a groove on the inner side of the alveolar border of the hard palate to the anterior palatine canal, where the terminal branch of the artery passes upward through the incisive canal (foramen of Stenson) to anastomose with the nasopalatine artery. Branches are distributed to the gums, the mucous membrane of the hard palate, and the palatine glands. In the palatine canal it gives off branches which descend in the accessory palatine canals to supply the soft palate and tonsil, anastomosing with the ascending palatine artery.

Applied Anatomy.—The position of the descending palatine artery on the hard palate should be borne in mind in performing an operation for the closure of a cleft in the hard palate, as the vessel is in danger of being wounded, and may give rise to formidable hemorrhage. In case it should be wounded it may be necessary to plug the posterior palatine canal in order to arrest the bleeding.

The **Vidian branch** (*a. canalis pterygoidei*) passes backward along the Vidian canal with the Vidian nerve. It is distributed to the upper part of the pharynx and Eustachian tube, sending a small branch into the tympanum, which anastomoses with the other tympanic arteries.

The **pterygopalatine**, a very small branch, runs backward through the pterygopalatine canal with the pharyngeal nerve, and is distributed to the upper part of the pharynx and Eustachian tube.

The **naso- or sphenopalatine** (*a. sphenopalatina*) passes through the sphenopalatine foramen into the cavity of the nose, at the back part of the superior meatus, and divides into several branches. One, the **nasopalatine**, or **artery of the septum**, courses obliquely downward and forward along the septum nasi, supplies the mucous membrane, and anastomoses in front with the terminal branch of the descending palatine; the other branches, two or three in number, are distributed to the lateral wall of the nose, the antrum, and to the ethmoidal and sphenoidal cells.

THE TRIANGLES OF THE NECK (Fig. 446).

The student having considered the relative anatomy of the large arteries of the neck and their branches, and the relations they bear to the veins and nerves, should now examine these structures collectively, as they present themselves in certain

regions of the neck, in each of which important operations are constantly being performed.

The side of the neck presents a somewhat quadrilateral outline, limited, *above*, by the lower border of the body of the mandible, and an imaginary line extending from the angle of the mandible to the mastoid process; *below*, by the prominent upper border of the clavicle; in *front*, by the median line of the neck; *behind*, by the anterior margin of the Trapezius muscle. This space is subdivided into two large triangles by the Sternomastoid muscle, which passes obliquely across the neck, from the sternum and clavicle below to the mastoid process above. The triangular space in front of this muscle is called the **anterior triangle**; and that behind it, the **posterior triangle**.

FIG. 446.—The triangles of the neck.

The **anterior triangle** is bounded, in *front*, by a line extending from the symphysis menti to the sternum; *behind*, by the anterior margin of the Sternomastoid; its *base*, directed upward, is formed by the lower border of the body of the mandible and a line extending from the angle of the mandible to the mastoid process; its *apex* is below, at the sternum. This space is subdivided into four smaller triangles by the Digastric muscle above and the anterior belly of the Omohyoid below. These smaller triangles are named from below upward, the **inferior carotid**, the **superior carotid**, the **submaxillary**, and the **suprahyoid triangles**.

The **inferior carotid triangle**, or the **triangle of necessity**, is bounded, in *front*, by the median line of the neck; *behind*, by the anterior margin of the Sternomastoid; *above*, by the anterior belly of the Omohyoid; and is covered by the integument, superficial fascia, Platysma, and deep fascia, ramifying between which are some of the descending branches of the superficial cervical plexus. Beneath these superficial structures are the Sternohyoid and Sternothyroid muscles, which, together with the anterior margin of the Sternomastoid, conceal the lower part of the common carotid artery.¹ The floor of this triangle is formed by the Longus

¹ Therefore, the common carotid artery and internal jugular vein are not, strictly speaking, contained in this triangle, since they are covered by the Sternomastoid muscle; that is to say, lie behind the anterior border of that muscle, which forms the posterior border of the triangle. But, as they lie very close to the structures which are really contained in the triangle, and whose position it is essential to remember in operating on this part of the artery, it has seemed expedient to study the relations of all these parts together.

colli muscle below and by the Scalenus anticus muscle above, between which muscles the vertebral artery and vein will be found passing into the foramen of the transverse process of the sixth cervical vertebra. A small portion of the origin of the Rectus capitis anticus major may also be seen on the floor of the space.

The common carotid artery is enclosed within its sheath, together with the internal jugular vein and vagus nerve; the vein lying on the outer side of the artery on the right side of the neck, but overlapping it below on the left side; the nerve lying between the artery and vein, on a plane posterior to both. In front of the sheath are a few filaments descending from the loop of communication between the descendens and communicans hypoglossi; behind the sheath are seen the inferior thyroid artery, the recurrent laryngeal nerve, and the sympathetic cord; and on its inner side, the trachea, the thyroid gland—much more prominent in the female than in the male—and the lower part of the larynx. By cutting into the upper part of this space and slightly displacing the Sternomastoid muscle the common carotid artery may be tied below the Omohyoid muscle.

The **superior carotid triangle**, or the **triangle of election**, is bounded, *behind*, by the Sternomastoid; *below*, by the anterior belly of the Omohyoid; and *above*, by the posterior belly of the Digastric muscle. It is covered by the integument, superficial fascia, Platysma, and deep fascia, ramifying between which are branches of the facial and superficial cervical nerves. Its floor is formed by parts of the Thyrohyoid and Hyoglossus muscles, and the Inferior and Middle constrictor muscles of the pharynx. This space, when dissected, is seen to contain the upper part of the common carotid artery, which bifurcates opposite the upper border of the thyroid cartilage into the external and internal carotid. These vessels are occasionally somewhat concealed from view by the anterior margin of the Sternomastoid muscle, which overlaps them. The external and internal carotid lie side by side, the external being the more anterior of the two. The following branches of the external carotid are also met with in this space, the superior thyroid running forward and downward, the lingual directly forward, the facial forward and upward, the occipital backward, and the ascending pharyngeal directly upward on the inner side of the internal carotid. The veins met with are the internal jugular, which lies on the outer side of the common and internal carotid arteries, and veins corresponding to the above-mentioned branches of the external carotid—viz., the superior thyroid, the lingual, facial, ascending pharyngeal, and sometimes the occipital, all of which accompany their corresponding arteries and terminate in the internal jugular. The nerves in this space are the following: In front of the sheath of the common carotid is the descendens hypoglossi. The hypoglossal nerve crosses both the internal and external carotids above, curving around the occipital artery at its origin. Within the sheath, between the artery and vein, and behind both, is the vagus nerve; behind the sheath, the sympathetic cord. On the outer side of the vessels the spinal accessory nerve runs for a short distance before it pierces the Sternomastoid muscle; and on the inner side of the external carotid, just below the hyoid bone, may be seen the internal branch of the superior laryngeal nerve; and, still more inferiorly, the external branch of the same nerve. The upper part of the larynx and lower part of the pharynx are also found in the front part of this space.

The **submaxillary triangle** corresponds to the part of the neck immediately beneath the body of the mandible. It is bounded, *above*, by the lower border of the body of the mandible and a line drawn from its angle to the mastoid process; *below*, by the posterior belly of the Digastric muscle and the Stylohyoid muscle; in *front*, by the anterior belly of the Digastric. It is covered by the integument, superficial fascia, Platysma, and deep fascia, ramifying between which are branches of the facial and ascending filaments of the superficial cervical nerves. Its floor is formed by the Mylohyoid and Hyoglossus muscles. This space contains, in front, the

submaxillary gland, superficial to which is the facial vein, while embedded in it are the facial artery, and its glandular branches; beneath this gland, on the surface of the Mylohyoid muscle, are the submental artery and the mylohyoid artery and nerve. The posterior part of this triangle is separated from the anterior part by the stylomaxillary ligament; it contains the external carotid artery, ascending deeply in the substance of the parotid gland; this vessel here lies in front of, and superficial to, the internal carotid, being crossed by the facial nerve, and gives off in its course the posterior auricular, temporal, and internal maxillary branches; more deeply are the internal carotid artery, the internal jugular vein, and the vagus nerve, separated from the external carotid by the Styloglossus and Stylopharyngeus muscles and the glossopharyngeal nerve.¹

The **suprahyoid triangle** is limited behind by the anterior belly of the Digastric, in front by the middle line of the neck between the symphysis menti and the hyoid bone, below by the body of the hyoid bone; its floor is formed by the Mylohyoid. It contains one or two lymph nodes and some small veins; the latter unite to form the anterior jugular vein.

The **posterior triangle** is bounded, in *front*, by the Sternomastoid muscle; *behind*, by the anterior margin of the Trapezius; its *base* corresponds to the middle third of the clavicle; its *apex*, to the occiput. The space is crossed, about an inch above the clavicle, by the posterior belly of the Omohyoid, which divides it unequally into two, an **upper or occipital** and a **lower or subclavian triangle**.

The **occipital triangle**, the larger division of the posterior triangle, is bounded, in *front*, by the Sternomastoid; *behind*, by the Trapezius; *below*, by the Omohyoid. Its floor is formed from above downward by the Splenius, Levator anguli scapulae, and the Middle and Posterior scaleni muscles. It is covered by the integument, the Platysma below, the superficial and deep fasciæ; the spinal accessory nerve is directed obliquely across the space from the Sternomastoid, which it pierces, to the under surface of the Trapezius; below, the descending branches of the cervical plexus and the transversalis colli artery and vein cross the space. A chain of lymph nodes is also found running along the posterior border of the Sternomastoid, from the mastoid process to the root of the neck.

The **subclavian triangle**, the smaller of the two posterior triangles, is bounded, *above*, by the posterior belly of the Omohyoid; *below*, by the clavicle, its *base*, directed forward, being formed by the Sternomastoid. The size of the subclavian triangle varies according to the extent of attachment of the clavicular portion of the Sternomastoid and Trapezius muscles, and also according to the height at which the Omohyoid crosses the neck above the clavicle. Its height also varies much according to the position of the arm, being much diminished by raising the limb, on account of the ascent of the clavicle, and increased by drawing the arm downward, when that bone is depressed. This space is covered by the integument, the Platysma, the superficial and deep fasciæ, and crossed by the descending branches of the cervical plexus. Just above the level of the clavicle the third portion of the subclavian artery curves outward and downward from the outer margin of the Scalenus anticus, across the first rib, to the axilla. Sometimes this vessel rises as high as an inch and a half above the clavicle, or to any point intermediate between this and its usual level. Occasionally it passes in front of the Scalenus anticus or pierces the fibres of that muscle. The subclavian vein lies behind the clavicle, and is usually not seen in this space; but it occasionally rises as high up as the artery, and has even been seen to pass with that vessel behind the Scalenus anticus. The brachial plexus of nerves lies above the artery, and in close contact with it. Passing transversely behind the clavicle are the supra-

¹ The remark made about the carotid triangle applies also to this one. The structures enumerated as contained in its posterior part lie, strictly speaking, beneath the muscles which form the posterior boundary of the triangle; but as it is very important to bear in mind their close relation to the parotid gland, all these parts are spoken of together.

scapular vessels, and traversing its upper angle in the same direction, the transversalis colli artery and vein. The external jugular vein runs vertically downward behind the posterior border of the Sternomastoid muscle, to terminate in the subclavian vein; it receives the transverse cervical and suprascapular veins, which occasionally form a plexus in front of the artery, and a small vein which crosses the clavicle from the cephalic. The small nerve to the Subclavius muscle also crosses this triangle about its middle. A lymph node is also found in the space. Its floor is formed by the first rib with the first digitation of the Serratus magnus.

FIG. 447.—The internal carotid and vertebral arteries. Right side.

The Internal Carotid Artery (A. Carotis Interna).

The **internal carotid artery** supplies the anterior part of the brain, the eye and its appendages, and sends branches to the forehead and nose. Its size in the

adult is equal to that of the external carotid, though in the child it is larger than that vessel. It is remarkable for the number of curvatures that it presents in different parts of its course. It occasionally has one or two flexures near the base of the skull, while in its passage through the carotid canal and along the side of the body of the sphenoid bone it describes a double curve which resembles somewhat the letter S.

In considering the course and relations of this vessel it may be conveniently divided into four portions—the **cervical, petrous, cavernous, and cerebral portions.**

Cervical Portion.—This portion of the internal carotid commences at the bifurcation of the common carotid, opposite the upper border of the thyroid cartilage, and runs perpendicularly upward, in front of the transverse processes of the upper three cervical vertebræ, to the carotid canal in the petrous portion of the temporal bone. It is comparatively superficial at its commencement, where it is contained in the superior carotid triangle, and lies behind and to the outer side of the external carotid, overlapped by the Sternomastoid and covered by the deep fascia, Platysma, and integument; it then passes beneath the parotid gland, being crossed by the hypoglossal nerve, the Digastric and Stylohyoid muscles, and the occipital and posterior auricular arteries. Higher up, it is separated from the external carotid by the Styloglossus and Stylopharyngeus muscles, the tip of the styloid process and the stylohyoid ligament, the glossopharyngeal nerve, and pharyngeal branch of the vagus.

Relations.—It is in relation, *behind*, with the Rectus capitis anticus major, the superior cervical ganglion of the sympathetic, and superior laryngeal nerve; *externally*, with the internal jugular vein and vagus nerve, the nerve lying on a plane posterior to the artery; *internally*, with the pharynx, tonsil, the superior laryngeal nerve, and ascending pharyngeal artery. At the base of the skull the glossopharyngeal, vagus, spinal accessory, and hypoglossal nerves lie between the artery and the internal jugular vein.

PLAN OF THE RELATIONS OF THE INTERNAL CAROTID ARTERY IN THE NECK.

In front.

Skin, superficial and deep fascia.
Platysma.
Sternomastoid.
Occipital and posterior auricular arteries.
Hypoglossal nerve.
Parotid gland.
Styloglossus and Stylopharyngeus muscles.
Glossopharyngeal nerve.
Pharyngeal branch of the vagus.

Externally.

Internal jugular vein.
Vagus nerve.

Internally.

Pharynx.
Superior laryngeal nerve.
Ascending pharyngeal artery.
Tonsil.

Behind.

Rectus capitis anticus major.
Sympathetic.
Superior laryngeal nerve.

Petrous Portion.—When the internal carotid artery enters the canal in the petrous portion of the temporal bone, it first ascends a short distance, then curves forward and inward, and again ascends as it leaves the canal to enter the cavity of

the skull between the lingula and petrosal process. In this canal the artery lies at first in front of the cochlea and tympanum; from the latter cavity it is separated by a thin, bony lamella. Farther forward it is separated from the Gasserian ganglion by a thin plate of bone, which forms the floor of the fossa for the ganglion and the roof of the horizontal portion of the canal. Frequently this bony plate is more or less deficient, and then the ganglion is separated from the artery by a fibrous membrane. The artery is separated from the bony wall of the carotid canal by a prolongation of the dura, and is surrounded by a number of small veins and by filaments of the carotid plexus, derived from the ascending branch of the superior cervical ganglion of the sympathetic.

Cavernous Portion.—The internal carotid artery in this part of its course is situated between the layers of the dura forming the cavernous sinus, but is covered by the lining membrane of the sinus. It at first ascends to the posterior clinoid process, then passes forward by the side of the body of the sphenoid bone, and again curves upward on the inner side of the anterior clinoid process, and perforates the dura, forming the roof of the sinus. In this part of its course it is surrounded by filaments of the sympathetic nerve, and has in relation with it externally the abducent nerve.

Cerebral Portion.—Having perforated the dura, on the inner side of the anterior clinoid process, the internal carotid passes between the optic and oculomotor nerves to the anterior perforated substance at the inner extremity of the sylvian fissure, where it gives off its terminal or cerebral branches. This portion of the artery has the optic nerve on its inner side, and the oculomotor nerve externally.

Peculiarities.—The length of the internal carotid varies according to the length of the neck, and also according to the point of bifurcation of the common carotid. Its origin sometimes takes place from the arch of the aorta; in such rare instances this vessel has been found to be placed nearer the middle line of the neck than the external carotid, as far upward as the larynx, when the latter vessel crossed the internal carotid. The course of the vessel, instead of being straight, may be very tortuous. A few instances are recorded in which this vessel was altogether absent; in one of these the common carotid passed up the neck, and gave off the usual branches of the external carotid, the cranial portion of the internal carotid being replaced by two branches of the internal maxillary, which entered the skull through the foramen rotundum and the foramen ovale and joined to form a single vessel.

Applied Anatomy.—The cervical part of the internal carotid is very rarely wounded. Mr. Cripps, in an interesting paper in the *Medico-Chirurgical Transactions*, compares the rareness of a wound of the internal carotid with one of the external carotid or its branches. It is, however, sometimes injured by a *stab* or *gunshot wound* in the neck, or even occasionally by a *stab* from *within the mouth*, as when a person receives a thrust from the end of a parasol or falls down with a tobacco-pipe in his mouth. It used to be believed that the internal carotid was occasionally wounded in the removal of the tonsil. Such an accident cannot happen if the artery is normally placed. The severe and sometimes fatal hemorrhage which has followed this operation in a few instances probably had as its source enlarged branches of the ascending pharyngeal, tonsillar, or ascending palatine arteries. Recently, however, Dr. Gwilym G. Davis, of Philadelphia, demonstrated a specimen in which the internal carotid could have been wounded by incision of the tonsil. The indications for ligation are *wounds*, when the vessel should be exposed by a careful dissection and tied above and below the bleeding point; and *aneurism*, which if non-traumatic may be treated by ligation of the common carotid, but if traumatic in origin by exposing the sac and tying the vessel above and below. The incision for ligation of the cervical portion of the internal carotid should be made along the anterior border of the Sternomastoid, from the angle of the mandible to the upper border of the thyroid cartilage. The superficial structures being divided and the Sternomastoid defined and drawn outward, the cellular tissue must be carefully separated and the posterior belly of the Digastric muscle and the hypoglossal nerve sought for as guides to the vessel. When the artery is found the external carotid should be drawn inward and the Digastric muscles upward, and the aneurism needle passed from without inward.

Obstruction of the internal carotid by *embolism* or *thrombosis* may give rise to symptoms of cerebral anemia and softening if the collateral circulation is ill-developed. The patient suffers from giddiness, with failure of mental powers, and convulsions, coma, or hemiplegia on the opposite side of the body, may be observed.

The **branches** given off from the internal carotid artery are:

From the <i>Petrous Portion</i>	{ Tympanic (internal or deep). Vidian.
From the <i>Cavernous Portion</i>	{ Arteriae Receptaculi. Anterior Meningeal. Ophthalmic.
From the <i>Cerebral Portion</i>	{ Anterior Cerebral. Middle Cerebral. Posterior Communicating. Anterior Choroid or Prechoroid.

The cervical portion of the internal carotid gives off no branches.

1. The **tympanic** (*ramus caroticotympanicus*) is a small branch from the petrous portion, which enters the cavity of the tympanum through a minute foramen in the carotid canal, and anastomoses with the tympanic branch of the internal maxillary, and with the stylomastoid artery.

FIG. 448.—The ophthalmic artery and its branches, the roof of the orbit having been removed.

2. The **Vidian** is a small, inconstant branch which passes through the Vidian canal and anastomoses with the Vidian branch of the internal maxillary artery.

3. The **arteriae receptaculi** are numerous small vessels, derived from the internal carotid in the cavernous sinus; they supply the hypophysis (pituitary body), the Gasserian ganglion, and the walls of the cavernous and inferior petrosal sinuses. Some of these branches anastomose with branches of the middle meningeal.

4. The **anterior meningeal** (*a. praeduralis, a. meningeal anterior*) is a small branch which passes over the lesser wing of the sphenoid to supply the dura of the

anterior fossa; it anastomoses with the dural branch from the posterior ethmoidal artery.

5. The **ophthalmic artery** (*a. ophthalmica*) arises from the internal carotid, just as that vessel is emerging from the cavernous sinus, on the inner side of the anterior clinoid process, and enters the orbit through the optic foramen, below and on the outer side of the optic nerve. It then passes over the nerve to the inner wall of the orbit and thence horizontally forward, beneath the lower border of the Superior oblique muscle, to a point behind the internal angular process of the frontal bone, where it divides into two terminal branches, the **frontal** and **nasal branches**. As the artery crosses the optic nerve it is accompanied by the nasal nerve, and is separated from the frontal nerve by the Rectus superior and Levator palpebrae superioris muscles.

Branches.—The branches of this vessel may be divided into an **orbital group**, which are distributed to the orbit and surrounding parts, and an **ocular group**, which supply the muscles and globe of the eye:

Orbital Group.

Lacrimal.
Supraorbital.
Posterior ethmoidal.
Anterior ethmoidal.
Internal palpebral.
Frontal.
Nasal.

Ocular Group.

Short ciliary.
Long ciliary.
Anterior ciliary.
Central artery of the retina.
Muscular.

The **lacrimal** (*a. lacrimalis*) is one of the largest branches derived from the ophthalmic, arising close to the optic foramen; not infrequently it is given off from the ophthalmic artery before it enters the orbit. It accompanies the lacrimal nerve along the upper border of the External rectus muscle, and is distributed to the lacrimal gland. Its terminal branches, escaping from the gland, are distributed to the eyelids and conjunctiva; of those supplying the eyelids, two are of considerable size and are named the **external palpebral** (*aa. palpebrales laterales*); they run inward in the upper and lower lids respectively, and anastomose with the *internal palpebral arteries*, forming an arterial circle in this situation. The lacrimal artery gives off one or two **malar branches**, one of which passes through a foramen in the malar bone, to reach the temporal fossa, and anastomoses with the deep temporal arteries; the other appears on the cheek through the malar foramen, and anastomoses with the transverse facial. A **recurrent** branch passes backward through the sphenoidal fissure to the dura, and anastomoses with a branch of the middle meningeal artery.

Peculiarities.—The lacrimal artery is sometimes derived from one of the anterior branches of the middle meningeal artery.

The **supraorbital artery** (*a. supraorbitalis*) arises from the ophthalmic as that vessel is crossing over the optic nerve. Ascending so as to arise above all the muscles of the orbit, it passes forward, with the supraorbital nerve, between the periosteum and Levator palpebrae muscle; and, passing through the supraorbital foramen, divides into a superficial and deep branch, which supply the integument, the muscles, and the pericranium of the forehead, anastomosing with the frontal, the anterior branch of the temporal, and the supraorbital artery of the opposite side. This artery in the orbit supplies the Superior rectus and the Levator palpebrae muscles, and sends a branch inward, across the pulley of the Superior oblique muscle, to supply the parts at the inner canthus. At the supraorbital foramen it frequently transmits a branch to the diploë.

The **ethmoidal branches** are two in number—**posterior** (*a. ethmoidalis posterior*) and **anterior** (*a. ethmoidalis anterior*). The **posterior ethmoidal artery**, which is the smaller, passes through the posterior ethmoidal foramen, supplies the posterior ethmoidal cells, and, entering the cranium, gives off a meningeal or dural branch,

FIG. 449.—The arteries of the base of the brain. The right half of the cerebellum and pons have been removed. N. B.—It will be noticed that the two anterior cerebral arteries have been drawn at a considerable distance from each other; this makes the anterior communicating artery appear very much longer than it really is.

which supplies the adjacent dura; and nasal branches which descend into the nose through apertures in the cribriform plate, anastomosing with branches of the sphenopalatine. The **anterior ethmoidal artery** accompanies the nasal nerve through the anterior ethmoidal foramen, supplies the anterior ethmoidal cells and frontal

sinuses, and, entering the cranium, gives off a dural branch which supplies the adjacent dura; and nasal branches, which descend into the nose, through the slit by the side of the crista galli, and, running along the groove on the under surface of the nasal bone, supply the skin of the nose.

The **internal palpebral arteries** (*aa. palpebrales mediales*), two in number, **superior** and **inferior**, arise from the ophthalmic, opposite the pulley of the Superior oblique muscle; they leave the orbit to encircle the eyelids near their free margin, forming a **superior tarsal arch** (*arcus tarseus superior*) and an **inferior tarsal arch** (*arcus tarseus inferior*), which lie between the Orbicularis muscle and the tarsal plates. The superior palpebral anastomoses, at the outer angle of the orbit, with the orbital branch of the temporal artery, and with the upper of the two external palpebral branches from the lacrimal artery; the inferior palpebral anastomoses,

FIG. 450.—Vascular area of the upper surface of the cerebrum. I. The part supplied by the external and inferior frontal artery. II. The part supplied by the ascending frontal. III. The part supplied by the ascending parietal. IV. The part supplied by the sphenoparietal artery. (After Duret.)

at the outer angle of the orbit, with the lower of the two external palpebral branches from the lacrimal and with the transverse facial artery, and at the inner side of the lid with a branch from the angular artery. From this last anastomosis a branch passes to the nasal duct, ramifying in its mucous membrane, as far as the inferior meatus.

The **frontal artery** (*a. frontalis*), one of the terminal branches of the ophthalmic, leaves the orbit at its inner angle with the supratrochlear nerve, and, ascending on the forehead, supplies the integument, muscles, and pericranium, anastomosing with the supraorbital artery and with the frontal artery of the opposite side.

The **nasal artery** (*a. dorsalis nasi*), the other terminal branch of the ophthalmic, emerges from the orbit above the tendo oculi, and, after giving a branch to the upper part of the lacrimal sac, divides into two branches, one of which crosses

the root of the nose, the **transverse nasal**, and anastomoses with the angular artery; the other, the **dorsalis nasi**, runs along the dorsum of the nose, supplies its outer surface, and anastomoses with the artery of the opposite side and with the lateral nasal branch of the facial.

The **ciliary arteries** (*a. ciliares*) are divisible into three groups—the **short**, **long**, and **anterior**. The **short ciliary arteries** (*aa. ciliares posteriores breves*), from six to twelve in number, *arise* from the ophthalmic or some of its branches; they surround the optic nerve as they pass forward to the posterior part of the eyeball, pierce the sclera around the entrance of the nerve, and supply the choroid coat and ciliary processes. The **long ciliary arteries** (*aa. ciliares posteriores longae*), two in number, pierce the posterior part of the sclera at some little distance from the optic nerve, and run forward, along each side of the eyeball, between the sclera and choroid, to the ciliary muscle, where they divide into two branches; these form an arterial circle, the **circulus major**, around the circumference of the iris, from which numerous radiating branches pass forward, in its substance, to its free margin, where they form a second arterial circle, the **circulus minor**, around

FIG. 451.—Vascular area of the internal surface of the cerebrum. I. The part supplied by the anterior internal frontal. II. The part supplied by the middle internal frontal. III. The part supplied by the posterior internal frontal. IV. The part supplied by the posterior temporal. V. The part supplied by the occipital, both terminal branches of the posterior cerebral. (After Duret.)

its pupillary margin. The **anterior ciliary arteries** (*aa. ciliares anteriores*) are derived from the muscular branches (see below); they pass to the front of the eyeball in company with the tendons of the Recti muscles, form a vascular zone beneath the conjunctiva, and then pierce the sclera a short distance from the cornea and terminate in the circulus major of the iris.

The **central artery of the retina** (*arteria centralis retinae*) is the first and one of the smallest branches of the ophthalmic artery. It runs for a short distance within the dural sheath of the optic nerve, but about half an inch behind the eyeball it pierces the optic nerve obliquely, and runs forward in the centre of its substance, and enters the globe of the eye through the porus opticus. Its mode of distribution will be described in the account of the anatomy of the eye.

The **muscular branches** (*rami musculares*), two in number, **superior** and **inferior**, frequently spring from a common trunk. The **superior**, the smaller, often wanting, supplies the Levator palpebrae, Superior rectus, and Superior oblique. The **inferior**, more constant in its existence, passes forward between the optic nerve and the Inferior rectus muscle, and is distributed to the External, Internal, and Inferior

recti, and Inferior oblique. This vessel gives off most of the anterior ciliary arteries. Additional muscular branches are given off from the lacrimal and supra-orbital arteries or from the ophthalmic itself.

(For the Circulus or Circle of Willis, the posterior cerebral artery, and the blood-vessels of the cerebellum, see page 619.)

The **anterior cerebral** (*a. praecerebralis*, *a. cerebri anterior*) arises from the internal carotid at the inner extremity of the sylvian fissure. It passes forward and inward across the anterior perforated substance, above the optic nerve, to the commencement of the intercerebral fissure. Here it comes into close relationship with the anterior cerebral artery of the opposite side, and the two vessels are connected by a short anastomosing trunk, about two lines, $\frac{1}{8}$ inch (4 mm.), in length, the **anterior communicating artery**. From this point the two vessels run side by side in the intercerebral fissure, curve around the genu of the corpus callosum, and, turning backward, continue along its upper surface to its posterior part, where they terminate by anastomosing with the posterior cerebral arteries.

FIG. 452.—Vascular area of the inferior surface of the cerebrum. I. The part supplied by the anterior temporal from the posterior cerebral artery. II. The part supplied by the posterior temporal from the posterior cerebral artery. III. The part supplied by the occipital from the posterior cerebral artery. (After Duret.)

Branches.—In their course the anterior cerebral arteries give off the following branches:

Antero-median ganglionic.
Inferior internal frontal.

Anterior internal frontal.
Middle internal frontal.

Posterior internal frontal.

The **antero-median ganglionic** are a group of small arteries which arise at the commencement of the anterior cerebral artery; they pierce the anterior perforated

substance and lamina terminalis, and supply the rostrum of the corpus callosum, the septum lucidum, and the head of the caudate nucleus.

The **inferior internal frontal branches**, two or three in number, are distributed to the orbital surface of the frontal lobe, where they supply the olfactory lobe, gyrus rectus, and internal orbital (mesorbital) convolution.

The **anterior internal frontal** supply a part of the mesal surface of the prefrontal region, and send branches over the edge of the hemisphere to the superfrontal and medifrontal gyre and upper part of the precentral gyre.

The **middle internal frontal** supplies the corpus callosum, the callosal gyre, the mesal surface of the superfrontal convolution, and the dorsal part of the precentral gyre.

The **posterior internal frontal** supplies the precuneus and adjacent outer surface of the hemisphere.

The **anterior communicating artery** (*a. praecommunicans*, *a. communicans anterior*) is a short branch, about 4 mm. in length, but of moderate size, connecting the two anterior cerebral arteries across the intercerebral fissure. Sometimes

FIG. 453.—The distribution of the middle cerebral artery. (After Charcot.)

this vessel is wanting, the two arteries joining to form a single trunk, which afterward divides. Or the vessel may be wholly or partially divided into two; frequently it is longer and smaller than usual. It gives off some of the antero-median ganglionic group of vessels, which are, however, principally derived from the anterior cerebral.

The **middle cerebral artery** (*a. medicerebralis*, *a. cerebri media*) (Fig. 453), the largest branch of the internal carotid, passes obliquely outward along the sylvian fissure, and divides opposite the island of Reil into its terminal branches.

Branches.—The branches of the middle cerebral artery are:

Antero-lateral ganglionic.
Inferior external frontal.
Ascending frontal.

Ascending parietal.
Parietotemporal.
Temporal.

The **antero-lateral ganglionic branches**, a group of small arteries which *arise* at the commencement of the middle cerebral artery, are arranged in two sets; one, the **internal striate**, passes upward through the inner segment of the lenticular nucleus, and supplies it, the caudate nucleus, and the internal capsule; the other,

the **external striate**, ascends through the outer segment of the lenticular nucleus, and supplies the caudate nucleus and the thalamus. One artery of this group (also called **lenticulostriate arteries**) is of larger size than the rest, and is of special importance, as being the artery in the brain most frequently ruptured; it has been termed by Charcot the **artery of cerebral hemorrhage**. It passes up between the lenticular nucleus and the external capsule, and ultimately ends in the caudate nucleus.

The **inferior external frontal** supplies the subfrontal convolution (**Broca's convolution**) and the outer part of the orbital surface of the frontal lobe.

The **ascending frontal** supplies the precentral gyre.

The **ascending parietal** is distributed to the postcentral convolution and the lower part of the superior parietal convolution.

The **parietotemporal** supplies the supramarginal and angular gyres, the super-temporal, and part of the mediotemporal gyre.

The **temporal branches**, two or three in number, are distributed to the outer surface of the temporal lobe.

The **posterior communicating artery** (*a. postcommunicans, a. communicans posterior*) runs backward from the internal carotid, and anastomoses with the posterior cerebral, a branch of the basilar. This artery varies considerably in size, being sometimes small, and occasionally so large that the posterior cerebral may be considered as arising from the internal carotid rather than from the basilar. It is frequently larger on one side than on the other. From the posterior half of this vessel are given off a number of small branches, the **postero-median ganglionic branches**, which, with similar vessels from the posterior cerebral, pierce the posterior perforated substance and supply the internal surfaces of the thalami and the walls of the third ventricle.

The **choroid artery** (*a. praehorioidea, a. chorioidea*) is a small but constant branch which *arises* from the back part of the internal carotid, near the posterior communicating artery. Passing backward and outward between the temporal lobe and the crus, it enters the descending horn of the lateral ventricle through the choroidal fissure and ends in the choroid plexus. It is distributed to the hippocampus, fimbria, velum interpositum, and choroid plexus.

THE ARTERIES OF THE BRAIN.

Investigations show that the mode of distribution of the vessels of the brain has an important bearing upon a considerable number of the anatomical lesions of which this part of the nerve system may be the seat; it is therefore important to consider a little more in detail the manner in which the cerebral vessels are distributed.

The cerebral arteries are derived from the internal carotid and the vertebral, which at the base of the brain form a remarkable anastomosis known as the **circle of Willis** (*circulus arteriosus*) (Fig. 454). It is formed in front by the anterior cerebral arteries, branches of the internal carotid, which are connected by the anterior communicating; behind by the two posterior cerebrals, branches of the basilar, which are connected on each side to the internal carotid by the posterior communicating (Fig. 449). The parts of the brain included within this arterial circle are the lamina terminalis, the chiasm or commissure of the optic nerves, the tuber cinereum, the corpora albicantia, and the posterior perforated substance. This arrangement of the vessels of the circle is not invariable; according to Windle, it is maintained in little more than half the recorded cases. In the other cases there are different variations.

The three trunks which together supply each cerebral hemisphere *arise* from

the circle of Willis. From its anterior part proceed the two anterior cerebrals, from its antero-lateral part the middle cerebrals, and from its posterior part the posterior cerebrals. Each of these principal arteries gives origin to two very different systems of secondary vessels. One of these systems has been named the **central ganglionic system**, and the vessels belonging to it supply the central ganglia of the brain; the other has been named the **cortical arterial system**, and its vessels ramify in the pia and supply the cortex and subjacent medullary substance. These two systems, although they have a common origin, do not communicate at any point of their peripheral distribution, and are entirely independent of each other. Though some of the arteries of the cortical system approach, at their terminations, the regions supplied by the central ganglionic system, no communication between the two sets of vessels takes place, and there is between the parts supplied by the two systems a borderland of diminished nutritive activity. In the brains of old people softening is especially apt to occur in this ill-nourished territory.

FIG. 454.—Diagram of the arterial circulation at the base of the brain. *I*. Antero-median group of ganglionic branches. *II*. Postero-median group. *III*. Right and left antero-lateral group. *IV*. Right and left postero-lateral group.

The Central Ganglionic System.—All the vessels belonging to this system are given off from the circle of Willis or from the vessels immediately after their origin from it, so that if a circle is drawn at a distance of about an inch from the circle of Willis, it will include the origin of all the arteries belonging to this system (Fig. 454). The vessels of this system form six principal groups: (I) The **antero-median group**, derived from the anterior cerebrals and anterior communicating; (II) the **postero-median group**, from the posterior cerebrals and posterior communicating; (III) the right and left **antero-lateral group**, from the middle cerebrals; and (IV) the right and left **postero-lateral group**, from the posterior cerebrals, after they have wound around the crura. The vessels belonging to this system are larger than those of the cortical system, and are what Cohnheim has termed **terminal arteries**—that is to say, vessels which from their origin to their termination neither supply nor receive any anastomotic branches, so that by one of the small vessels only a limited area of the central ganglia can be injected; and the injection cannot

be driven beyond the area of the part supplied by the particular vessel which is the subject of the experiment.

The Cortical Arterial System.—The vessels forming this system are the terminal branches of the anterior, middle, and posterior cerebral arteries, described above. These vessels divide and ramify in the substance of the pia, and give off nutrient arteries which penetrate the cortex perpendicularly. These nutrient vessels are divisible into two classes—the long and short. The **long**—or, as they are sometimes called, the **medullary**—arteries pass through the gray substance to penetrate the centrum ovale to the depth of about an inch and a half, without intercommunicating otherwise than by very fine capillaries, and thus constitute so many

FIG. 455.—Distribution of the cortical arteries. 1. Medullary arteries. 1'. Group of medullary arteries in the sulcus between two adjacent convolutions. 1''. Arteries situated among the short association fibres. 2. Cortical arteries. a. Capillary network with fairly wide meshes, situated beneath the pia. b. Network with more compact, polygonal meshes, situated in the cortex. c. Transitional network, with wider meshes. d. Capillary network in the white substance. (After Charcot.)

independent small systems. The **short vessels** are confined to the cortex, where they form with the long vessels a compact network in the middle zone of the gray substance, the outer and inner zones being sparingly supplied with blood (Fig. 455). The vessels of the cortical arterial system are not so strictly terminal as those of the central ganglionic system, but they approach this type very closely, so that injection of one area from the vessel of another area, though it may be possible, is frequently very difficult, and is only effected through vessels of small caliber. As a result of this, obstruction of one of the main branches or its divisions may have the effect of producing softening in a very limited area of the cortex.

The Vertebral Artery (*A. Vertebralis*).

The **vertebral artery** (*a. vertebralis*) (Figs. 447 and 456) is generally the first and largest branch of the subclavian; in rare instances it springs independently from the arch of the aorta. It *arises* from the upper and back part of the first portion of the vessel, and, passing upward, enters the foramen in the transverse process of

the sixth cervical vertebra,¹ and ascends through the foramina in the transverse processes of all the vertebræ above this. Above the upper border of the axis it inclines outward and upward to the foramen in the transverse process of the atlas, through which it passes; it then winds backward behind its articular process, runs in a deep groove on the upper surface of the posterior arch of this bone (Fig. 16), and, passing beneath the posterior occipito-atlantal ligament (Figs. 224 and 227), pierces the dura and arachnoid, and enters the skull through the foramen magnum. It then passes forward and upward, inclining from the lateral aspect to the front of the medulla oblongata. It unites in the middle line with the vessel of the opposite side at the lower border of the pons to form the **basilar artery** (Fig. 449).

Relations.—At its origin it is situated behind the internal jugular and vertebral veins, and is crossed by the inferior thyroid artery; it lies between the Longus colli and Scalenus anticus muscles, having the thoracic duct in front of it on the left side. It rests on the transverse process of the seventh cervical vertebra and the sympathetic cord. Within the foramina formed by the transverse processes of the vertebræ it is accompanied by a plexus of nerves from the inferior cervical ganglion of the sympathetic, and is surrounded by a dense plexus of veins which unite to form the vertebral vein at the lower part of the neck. It is situated in front of the cervical nerves, as they issue from the intervertebral foramina. While winding around the articular process of the atlas, it is contained in the **suboccipital triangle**—a triangular space formed by the Rectus capitis posticus major, the Obliquus capitis superior and the Obliquus capitis inferior muscles. The suboccipital nerve here lies between the artery and the posterior arch of the atlas. Within the skull, as the artery winds around the oblongata, it is placed between the hypoglossal nerve and the anterior root of the suboccipital nerve, beneath the first digitation of the ligamentum denticulatum, and finally ascends between the basilar process of the occipital bone and the anterior surface of the medulla oblongata.

Applied Anatomy.—The vertebral artery has been tied in several instances. (1) For wounds or traumatic aneurism; (2) after ligation of the innominate, either immediately to prevent hemorrhage, or later on to arrest bleeding where it has occurred at the seat of ligation. The *operation of ligation of the vertebral* is performed by making an incision along the posterior border of the Sternomastoid muscle, just above the clavicle. The muscle is pulled to the inner side, and the anterior tubercle of the transverse process of the sixth cervical vertebra is sought for. A deep layer of fascia being now divided, the interval between the Scalenus anticus and the Longus colli muscles just below their attachment to the tubercle is defined, and the artery and vein are found in the interspace. The vein is to be drawn to the outer side, and the aneurism needle is passed from without inward. Drs. Ramskill and Bright have pointed out that severe pain at the back of the head may be symptomatic of disease of the vertebral artery just before it enters the skull. This is explained by the close connection of the artery with the suboccipital nerve in the groove on the posterior arch of the atlas. Disease of the same artery has been also said to affect speech, from pressure on the hypoglossal nerve where it is in relation with the vessel, leading to paralysis of the muscles of the tongue.

Branches.—These may be divided into two sets—those given off in the neck and those within the cranium.

Cervical Branches.

Spinal rami, or Lateral spinal.
Muscular.

Cranial Branches.

Posterior meningeal.
Anterior spinal, or Ventral spinal.
Posterior spinal, or Dorsal spinal.
Posterior inferior cerebellar.
Bulbar.

The **spinal branches** (*rami spinales*) enter the vertebral canal through the intervertebral foramina and divide into two branches. Of these, one passes along the roots of the nerves to supply the spinal cord and its membranes, anastomosing with the other arteries of the spinal cord; the other divides into an ascending and

¹ The vertebral artery sometimes enters the foramen in the transverse process of the fifth vertebra. Dr. Smyth, who tied this artery in the living subject, found it, in one of his dissections, passing into the foramen in the seventh vertebra.

a descending branch, which unite with similar branches from the artery above and below, so that two lateral anastomotic chains are formed on the posterior surface of the vertebræ near the attachment of the pedicles. From these anastomotic chains branches are given off to supply the periosteum and the bodies of the vertebræ, and to communicate with similar branches from the opposite side; from these communicating branches small branches are given off which join similar branches above and below, so that a central anastomotic chain is formed on the posterior surface of the bodies of the vertebræ.

Muscular branches are given off to the deep muscles of the neck, where the vertebral artery curves around the articular process of the atlas. They anastomose with the occipital and with the ascending and deep cervical arteries.

The **posterior meningeal** (*ramus meningeus*) is a small branch given off from the vertebral opposite the foramen magnum. It ramifies between the bone and dura in the cerebellar fossæ, and supplies the falx cerebelli. It is frequently represented by two small branches.

The **anterior or ventral spinal** (*a. spinalis ventralis*, *a. spinalis anterior*) is a small branch which *arises* near the termination of the vertebral, and, descending in front of the medulla oblongata, unites with its fellow on the opposite side at about the level of the foramen magnum. One of these vessels is usually larger than the other, but occasionally they are about equal in size. The single trunk thus formed descends on the front of the spinal cord, and is reinforced by a succession of small branches which enter the vertebral canal through the intervertebral foramina; these branches are derived from the vertebral artery and the ascending cervical branch of the inferior thyroid artery in the neck; from the intercostal in the thoracic region; and from the lumbar, iliolumbar, and lateral sacral arteries in the lower part of the vertebral column. They unite, by means of ascending and descending branches, to form a single terminal artery, which extends as far as the lower part of the spinal cord. This vessel is placed in the pia along the anterior median fissure; it supplies that membrane and the substance of the cord, and sends off branches at its lower part to be distributed to the cauda equina, and ends on the central fibrous prolongation of the cord.

The **posterior or dorsal spinal** (*a. spinalis dorsalis*, *a. spinalis posterior*) *arises* from the vertebral at the side of the medulla oblongata; passing backward to the posterior aspect of the spinal cord, it descends on each side, lying behind the posterior roots of the spinal nerves, and is reinforced by a succession of small branches which enter the vertebral canal through the intervertebral foramina, and by which it is continued to the lower part of the cord and to the cauda equina. Branches from the posterior spinal arteries form a free anastomosis around the posterior roots of the spinal nerves, and communicate, by means of very tortuous transverse branches, with the vessel of the opposite side. Close to its origin each gives off an ascending branch, which terminates at the side of the fourth ventricle.

Applied Anatomy.—Bleeding into the spinal membranes or into the substance of the spinal cord itself is not common, but may occur from injuries received at birth when labor is unduly prolonged or instruments are used. It is also met with in chronic insanity, and in tetanus and strychnine poisoning.

The **posterior inferior cerebellar artery** (*a. postcerebellaris*, *a. cerebelli inferior posterior*) (Fig. 449), the largest branch of the vertebral, winds backward around the upper part of the medulla oblongata, passing between the origin of the vagus and spinal accessory nerves, over the restiform body to the under surface of the cerebellum, where it divides into two branches—an **internal**, which is continued backward to the notch between the two hemispheres of the cerebellum; and an **external**, which supplies the under surface of the cerebellum as far as its outer border, where it anastomoses with the anterior inferior cerebellar and the

superior cerebellar branches of the basilar artery. Branches from this artery supply the choroid plexus of the fourth ventricle.

The **bulbar arteries** comprise several minute vessels which spring from the vertebral and its branches and are distributed to the medulla oblongata.

The **basilar artery** (*a. basilaris*) (Fig. 449), so named from its position at the base of the skull, is a single trunk formed by the junction of the two vertebral arteries; it extends from the posterior to the anterior border of the pons, lying in the median pontile groove, under cover of the arachnoid. It ends by dividing into the two **posterior cerebral arteries**.

Branches.—Its branches on either side are the following:

Transverse.	Anterior inferior cerebellar.
Internal auditory.	Superior cerebellar.
	Posterior cerebral.

The **transverse or pontile branches** (*rami ad pontem*) are a number of small vessels which come off at right angles on either side of the basilar artery and supply the pons and adjacent parts of the brain.

The **internal auditory** (*a. auditiva interna*), a long slender branch, *arises* from near the middle of the artery; it accompanies the corresponding auditory nerve into the internal auditory meatus and is distributed to the internal ear.

The **anterior inferior cerebellar artery** (*a. medicerebellaris*, *a. cerebelli inferior anterior*) passes backward, to be distributed to the anterior part of the under surface of the cerebellum, anastomosing with the posterior inferior cerebellar branch of the vertebral.

The **superior cerebellar artery** (*a. praecerebellaris*, *a. cerebelli superior*) *arises* near the termination of the basilar. It passes outward, immediately behind the oculomotor nerve, which separates it from the posterior cerebral artery, winds around the crus, close to the trochlear nerve, and, arriving at the upper surface of the cerebellum, divides into branches which ramify in the pia and, reaching the circumference of the cerebellum, anastomose with the branches of the inferior cerebellar artery. Several branches are given to the epiphysis, the valve of Vieussens, and the velum interpositum.

The **posterior cerebral artery** (*a. postcerebralis*, *a. cerebri posterior*) (Figs. 449 and 454) is larger than the preceding, from which it is separated near its origin by the oculomotor nerve. Passing outward, parallel to the superior cerebellar artery, and receiving the posterior communicating from the internal carotid, it winds around the crus, and passes to the under surface of the temporal lobe of the cerebrum, and divides up into branches for the supply of the temporal and occipital lobes.

The **branches** of the posterior cerebral artery are:

Ganglionic	{	Postero-median ganglionic.	Cortical	{	Anterior temporal.
		Posterior choroid.			Posterior temporal.
		Postero-lateral ganglionic.			Occipital.

Ganglionic.—The **postero-median ganglionic branches** (Fig. 454) are a group of small arteries which *arise* at the commencement of the posterior cerebral artery; these, with similar branches from the posterior communicating, pierce the posterior perforated substance, and supply the internal surfaces of the thalamus and the walls of the third ventricle. The **posterior choroid** enters the interior of the brain beneath the splenium of the corpus callosum, and supplies the velum interpositum and the choroid plexus. The **postero-lateral ganglionic branches** are a group of small arteries which *arise* from the posterior cerebral artery, after it has turned around the crus; they supply a considerable portion of the thalamus.

Cortical.—The cortical branches are the **anterior temporal branches**, to the basal surface of the anterior portion of the temporal lobe; the **posterior temporal branches**, to the external surface of the occipital lobe and the subtemporal convolution; and the **occipital branches**, to the mesal and lateral surfaces of the occipital lobe.

ARTERIES OF THE UPPER EXTREMITY.

The artery which supplies the upper extremity continues as a single trunk from its commencement down to the elbow, but different portions of it have received different names according to the region through which it passes. That part of the vessel which extends from its origin to the outer border of the first rib is termed the **subclavian artery**; beyond this point to the lower border of the axilla it is termed the **axillary artery**; and from the lower margin of the axillary space to the bend of the elbow it is termed the **brachial artery**; here the single trunk terminates by dividing into two branches, the **radial** and **ulnar**.

THE SUBCLAVIAN ARTERY (A. SUBCLAVIA) (Fig. 456).

On the right side the **subclavian artery** *arises* from the innominate artery opposite the right sternoclavicular articulation; on the left side it *arises* from the arch of the aorta. The two vessels, therefore, in the first part of their course, differ in length, direction, and relation with neighboring structures.

In order to facilitate the description of these vessels, more especially from a surgical point of view, each subclavian artery has been divided into three parts.

The *first portion*, on the *right side*, passes upward and outward from the origin of the vessel to the inner border of the *Scalenus anticus*. On the *left side* it ascends nearly vertically, to gain the inner border of that muscle. The *second part* passes outward, behind the *Scalenus anticus*; and the *third part* passes from the outer margin of that muscle, beneath the clavicle, to the outer border of the first rib, where it becomes the axillary artery. The first portion of these two vessels differs so much in its course and in its relations with neighboring parts that it will be described separately. The second and third parts are alike on the two sides.

FIG. 456.—Plan of the branches of the right subclavian artery.

First Part of the Right Subclavian Artery (Fig. 457).—The first part of the right subclavian artery *arises* from the innominate artery, opposite the upper part of the right sternoclavicular articulation, and passes upward and outward to the inner margin of the Scalenus anticus muscle (Fig. 457). It ascends a little above the clavicle, the extent to which it does so varying in different cases.

Relations.—It is covered, *in front*, by the integument, superficial fascia, Platysma, deep fascia, the clavicular origin of the Sternomastoid, the Sternohyoid, and the Sternothyroid muscles, and another layer of deep fascia. It is crossed by the internal jugular and vertebral veins, and by the vagus nerve and the cardiac branches of the vagus and sympathetic nerves. A loop of the sympathetic nerve itself also crosses the artery, forming a ring (*ansa subclavia*) around the vessel. The anterior jugular vein passes outward in front of the artery, but is not in contact with it, being separated from it by the Sternohyoid and Sternothyroid muscles. *Below* and *behind* the artery is the pleura, which separates it from the apex of the lung; *behind* is the gangliated cord of the sympathetic, the Longus colli muscle and the first thoracic vertebra. The right recurrent laryngeal nerve winds around the lower and back part of the vessel.

FIG. 457.—The subclavian artery, showing its relations. (From a preparation in the Museum of the Royal College of Surgeons of England.)

PLAN OF THE RELATIONS OF FIRST PORTION OF THE RIGHT SUBCLAVIAN ARTERY.

 First thoracic vertebra.

First Part of the Left Subclavian Artery (Figs. 431 and 432).—The first part of the left subclavian artery arises from the arch of the aorta, behind the left common carotid, and at the level of the fourth thoracic vertebra; it ascends nearly vertically to the root of the neck and then arches outward to the inner margin of the *Scalenus anticus* muscle.

Relations.—It is in relation, *in front*, with the vagus, cardiac, and phrenic nerves, which lie parallel with it, the left carotid artery, left internal jugular and vertebral veins, and the commencement of the left innominate vein, and is covered by the *Sternothyroid*, *Sternohyoid*, and *Sternomastoid* muscles. A loop of the sympathetic encircles the artery, forming the *ansa subclavia*. *Behind*, it is in relation with the oesophagus, thoracic duct, inferior cervical ganglion of the sympathetic, and *Longus colli* muscle; higher up, however, the oesophagus and thoracic duct lie to its right side; the latter ultimately arching over the vessel to join the angle of union between the subclavian and internal jugular veins. To its *inner side* are the oesophagus, trachea, thoracic duct, and left recurrent laryngeal nerve; to its *outer side*, the left pleura and lung.

Second and Third Parts of the Subclavian Artery (Figs. 435 and 457).—The second portion of the subclavian artery lies behind the *Scalenus anticus* muscle; it is very short, and forms the highest part of the arch described by that vessel.

Relations.—It is covered, *in front*, by the skin, superficial fascia, *Platysma*, deep cervical fascia, the *Sternomastoid* and the *Scalenus anticus* muscles. On the right side the phrenic nerve is separated from the second part of the artery by the *Scalenus anticus* muscle, while on the left side the nerve crosses the first part of the artery immediately to the inner edge of the muscle. *Behind*, it is in relation with the pleura and the *Scalenus medius* muscle. *Above*, is the brachial plexus of nerves; *below*, the pleura. The subclavian vein lies below and in front of the artery, separated from it by the *Scalenus anticus* muscle.

Below.

Pleura.

Behind.

Pleura and Middle *Scalenus*.

The third portion of the subclavian artery passes downward and outward from the outer margin of the *Scalenus anticus* muscle to the outer border of the first rib, where it becomes the axillary artery. This portion of the vessel is the most superficial, and is contained in the subclavian triangle (see page 608).

Relations.—It is covered, *in front*, by the skin, the superficial fascia, the *Platysma*, the descending claviclar branches of the cervical plexus, and the deep cervical fascia; by the clavicle, the *Subclavius* muscle, the suprascapular artery and vein, and the transverse cervical vein; the nerve to the *Subclavius* muscle passes vertically downward in front of the artery. The external jugular vein crosses the artery at its inner side, and receives the suprascapular and transverse cervical veins, which frequently form a plexus in front of it. The subclavian vein is below and in front of the artery, lying close behind the clavicle. *Behind*, it lies on the Middle *Scalenus* muscle and the lowest cord of the brachial plexus, formed by the union of the last cervical and first thoracic nerves. *Above* and to its outer side are the upper trunks of the brachial plexus and the *Omohyoid* muscle. *Below*, it rests on the upper surface of the first rib, or on the cervical rib if one be present.

Peculiarities.—The subclavian arteries vary in their origin, their course, and the height to which they rise in the neck.

The origin of the right subclavian from the innominate takes place, in some cases, above the sternoclavicular articulation, and occasionally, but less frequently, in the cavity of the thorax, below that point. Or the artery may arise as a separate trunk from the arch of the aorta. In such cases it may be either the first, second, third, or even the last branch derived from that vessel; in the majority of cases it is the first or last, rarely the second or third. When it is the first branch, it occupies the ordinary position of the innominate artery; when the second or third, it gains its usual position by passing behind the right carotid; and when the last branch, it arises from the left extremity of the arch, at its upper or back part, and passes obliquely toward the right side, usually behind the trachea, œsophagus, and right carotid, sometimes between the œsophagus and trachea to the upper border of the first rib, whence it follows its ordinary course. Its manner of development is such that the inferior laryngeal nerve is not looped under the vessel, but passes in a nearly straight course on its way to the larynx. In very rare instances this vessel arises from the thoracic aorta, as low down as the fourth thoracic vertebra. Occasionally it perforates the *Scalenus anticus* muscle; more rarely it passes in front of that muscle. Sometimes the subclavian vein passes with the artery behind the *Scalenus anticus* muscle. The artery may ascend as high as an inch and a half above the clavicle or any intermediate point between this and the upper border of the bone, the right subclavian usually ascending higher than the left.

The left subclavian is occasionally joined at its origin with the left common carotid.

Surface Marking.—The course of the subclavian artery in the neck may be mapped out by describing a curve, with its convexity upward at the base of the posterior triangle. The inner end of this curve corresponds to the sternoclavicular joint, the outer end of the centre of the

lower border of the clavicle. The curve is to be drawn with such an amount of convexity that its mid-point reaches half an inch above the upper border of the clavicle. The left subclavian artery is more deeply placed than the right in the first part of its course, and, as a rule, does not reach quite as high a level in the neck. It should be borne in mind that the posterior border of the Sternomastoid muscle corresponds to the outer border of the Scalenus anticus muscle, so that the third portion of the artery, that part most accessible for operation, lies immediately external to the posterior border of the Sternomastoid muscle.

Applied Anatomy.—The relations of the subclavian arteries of the two sides having been examined, the student should direct his attention to a consideration of the best position in which compression of the vessel may be effected, or in what situation a ligature may be best applied in cases of aneurism or wound.

Compression of the subclavian artery is required in cases of operation about the shoulder, in the axilla, or at the upper part of the arm; and the student will observe that there is only one situation in which it can be effectually applied—viz., where the artery passes across the upper surface of the first rib. In order to compress the vessel in this situation, the shoulder should be depressed, and the surgeon, grasping the side of the neck, should press with his thumb in the angle formed by the posterior border of the Sternomastoid with the upper border of the clavicle, downward, backward, and inward against the rib; if from any cause the shoulder cannot be sufficiently depressed, pressure may be made from before backward, so as to compress the artery against the Scalenus medius muscle and the transverse process of the seventh cervical vertebra. In appropriate cases a preliminary incision may be made through the cervical fascia, and the finger may be pressed down directly upon the artery.

Ligation of the subclavian artery may be required in cases of wounds or of aneurism in the axilla, or in cases of aneurism on the cardiac side of the point of ligation; and the third part of the artery is that which is most favorable for an operation, on account of its being comparatively superficial and most remote from the origin of the large branches. In those cases where the clavicle is not displaced, this operation may be performed with comparative facility; but where the clavicle is pushed up by a large aneurismal tumor in the axilla the artery is placed at a great depth from the surface, which materially increases the difficulty of the operation. Under these circumstances it becomes a matter of importance to consider the height to which this vessel reaches above the bone. In ordinary cases its arch is about half an inch above the clavicle, occasionally it is as high as an inch and a half, and sometimes so low as to be on a level with the upper border of the clavicle. If the clavicle is displaced, these variations will necessarily make the operation more or less difficult, according as the vessel is more or less accessible.

The procedure in the operation of tying the *third portion* of the subclavian artery is as follows: The patient being placed on a table in the supine position, with the head drawn over to the opposite side and the shoulder depressed as much as possible, the integument should be drawn downward over the clavicle, and an incision made through it, upon that bone, from the anterior border of the Trapezius to the posterior border of the Sternomastoid, to which may be added a short vertical incision meeting the inner end of the preceding. The object in drawing the skin downward is to avoid any risk of wounding the external jugular vein, for as it perforates the deep fascia above the clavicle, it cannot be drawn downward with the skin. The soft parts should now be allowed to glide up, and the cervical fascia should be divided upon a director, and if the interval between the Trapezius and Sternomastoid muscles be insufficient for the performance of the operation, a portion of one or both may be divided. The external jugular vein will now be seen toward the inner side of the wound; this and the suprascapular and transverse cervical veins, which terminate in it, should be held aside. If the external jugular vein is at all in the way and exposed to injury, it should be tied in two places and divided. The suprascapular artery should be avoided, and the Omohyoid muscle held aside if necessary. In the space beneath this muscle careful search must be made for the vessel; a layer of deep fascia and some connective tissue having been divided carefully, the outer margin of the Scalenus anticus muscle must be felt for, and, the finger being guided by it to the first rib, the pulsation of the subclavian artery will be felt as it passes over the rib. The sheath of the vessels having been opened, the aneurism needle may then be passed around the artery from above downward and inward, so as to avoid including any of the branches of the brachial plexus. If the clavicle is so raised by the tumor that the application of the ligature cannot be effected in this situation, the artery may be tied above the first rib, or even behind the Scalenus anticus muscle; the difficulties of the operation in such a case will be materially increased, on account of the greater depth of the artery and the alteration in position of the surrounding parts.

The *second part* of the subclavian artery, from being that portion which rises highest in the neck, has been considered favorable for the application of the ligature when it is difficult to tie the artery in the third part of its course. There are, however, many objections to the operation in this situation. It is necessary to divide the Scalenus anticus muscle, upon which lies the phrenic nerve, and at the inner side of which is situated the internal jugular vein; and a wound of either of these structures might lead to the most dangerous consequences. Again, the artery is in contact, below, with the pleura, which must also be avoided; and, lastly, the

proximity of so many of its large branches arising internal to this point must be a still further objection to the operation. In cases, however, where the sac of an axillary aneurism encroaches on the neck, it may be necessary to divide the outer half or two-thirds of the *Scalenus anticus* muscle, so as to place the ligature on the vessel at a greater distance from the sac. The operation is performed exactly in the same way as a ligation of the third portion, until the *Scalenus anticus* is exposed, when it is to be divided on a director (never to a greater extent than its outer two-thirds), and it immediately retracts. The operation is therefore merely an extension of ligation of the third portion of the vessel.

In those cases of aneurism of the axillary or subclavian artery in which the aneurism encroaches upon the outer portion of the *Scalenus* muscle to such an extent that a ligature cannot be applied in that situation, it may be deemed advisable, as a last resource, to tie the first portion of the subclavian artery. On the left side this operation has been regarded as almost impracticable; the great depth of the artery from its surface, its intimate relation with the pleura, and its close proximity to the thoracic duct and to so many important veins and nerves, presents a series of difficulties which it is very difficult to overcome. Nevertheless, it has been successfully done several times. The main objection to the operation in this situation is the smallness of the interval which usually exists between the commencement of the vessel and the origin of the nearest branch. The operation may be performed in the following manner: The patient being placed on the table in the supine position with the neck extended, an incision should be made along the upper border of the inner part of the clavicle, and a second along the inner border of the *Sternomastoid*, meeting the former at an angle. The attachment of both heads of the *Sternomastoid* must be divided on a director and turned outward; a few small arteries and veins, and occasionally the anterior jugular vein, must be avoided, or, if necessary, ligated in two places and divided, and the *Sternohyoid* and *Sternothyroid* muscles are to be divided in the same manner as the preceding muscle. After tearing through the deep fascia, the internal jugular vein will be seen crossing the subclavian artery; this should be pressed aside and the artery secured by passing the needle from below upward, by which the pleura is more effectually avoided. The exact position of the *vagus*, the recurrent laryngeal, the phrenic and sympathetic nerves should be remembered, and the ligature should be applied near the origin of the vertebral, in order to afford as much room as possible for the formation of a coagulum between the ligature and the origin of the vessel. It should be remembered that the right subclavian artery is occasionally deeply placed in the first part of its course when it arises from the left side of the aortic arch, and passes in such cases behind the *oesophagus* or between it and the trachea.

Branches.—The branches given off from the subclavian artery are:

Vertebral.
Thyroid axis.

Internal mammary.
Superior intercostal.
